

# Principles and General Considerations

## 1

### Principles of Parasitism: Host–Parasite Interactions

JUAN P. OLANO  
PETER F. WELLER  
RICHARD L. GUERRANT  
DAVID H. WALKER

#### INTRODUCTION

The relationship between two living organisms can be classified as parasitic, symbiotic, or commensal.<sup>1–3</sup> This same classification scheme can be used to describe relationships between microorganisms and more complex living organisms that act as hosts. The term *parasite* is used here in its broad sense to mean a microorganism interacting with another organism (either vertebrate or invertebrate) in the same ecologic niche.

The following definitions are used in this chapter:

*Parasitism*: Association between two different organisms wherein one benefits at the expense of the other. All infectious agents causing illness belong to this category.

*Commensalism*: Association between two organisms in which one derives benefit from the other without causing it any harm. This intermediate category is not uniformly accepted. Often, upon detailed analysis, the relationship turns out to be either parasitic or symbiotic.<sup>2</sup>

*Symbiosis* or *mutualism*: Both organisms benefit from the relationship. The type of relationship also depends on host factors. For example, bacteria normally inhabiting the bowel live in an apparent commensal or (by inhibiting potential pathogens) symbiotic relationship with humans. However, in cases of cirrhosis with consequent hepatic

insufficiency, bacteria can become a dangerous source of ammonia that leads to hepatic encephalopathy. A commensal relationship can be transformed into a potentially harmful one. In malnourished people with borderline deficiencies of B-complex vitamins, clinical beriberi can be triggered by administration of broad-spectrum antibiotics. Normally, in this situation bacteria play a symbiotic role by supplying a significant amount of B-complex vitamins.<sup>2</sup>

#### MICROBIAL FACTORS

##### Principles of Microbial Evolution and Classification

The earth is approximately 4.5 to 5 billion years old. There is good fossil evidence of microbial life approximately 3.5 billion years ago. Microbial life (stromatolites) was mostly photosynthetic, unicellular, and anaerobic.<sup>1,4</sup> Eukaryotes, bacteria, and archaea evolved from a still hypothetical universal common ancestor.<sup>5–7</sup> Eukaryotes then evolved into protozoans, metazoans, plants, and animals, as we know them today. Moreover, there is strong evidence that primitive eukaryotic cells established relationships with bacterial organisms that later evolved into cytoplasmic organelles, such as chloroplasts in plants and mitochondria in animals.<sup>8</sup>

To put things into perspective, approximately five-sixths of the history of life on Earth has been exclusively microbial. Human beings appeared on the planet only 2 million years ago as very late newcomers to the biosphere. Life was initially anaerobic, but with the appearance of photosynthetic organisms and chloroplasts, oxygen was released into the atmosphere for the first time.<sup>9</sup> Radiation in the upper atmosphere created the ozone layer from molecular oxygen, which then shielded the earth's surface from dangerous radiation. Nucleic acids were therefore protected from harmful mutations. Organisms had to evolve to survive in the presence of oxygen. A few of the ancient anaerobes were able to survive in the highly oxidant atmosphere, and they represent the anaerobes as we know them today.

The phylogeny of living organisms is based on molecular approaches, particularly analysis of ribosomal RNA.<sup>5,6,10</sup> Because of the antiquity of the protein synthesis machinery, these molecules appear to be excellent evolutionary clocks. For prokaryotes, the 16S subunit of ribosomes appears to be the most useful for classification purposes. The number of microbes in the world is tremendous, and relatively few are pathogenic to humans.

Viruses deserve special comment because of their molecular simplicity and at the same time their importance as human pathogens and as possible agents of hereditary changes and cancer.<sup>11,12</sup> A virus is a genetic element with either DNA or

RNA coated by protein of viral origin and sometimes enveloped by lipid material of host origin. Some viruses have enzymes that are necessary for their replication. The only criterion that these organisms fulfill to be considered living organisms is that of reproduction. They are inert particles when outside of the host cell, and once they have access into a cell they become active and the cell is subverted to produce more viral particles. Sometimes the cell dies in the process, and sometimes the relationship is stable. Viral hosts include bacteria, protozoa, animals, and plants.

The classification of viruses is based on different criteria than the ones used for other organisms. There are multiple ways to classify viruses; a simple one is based on the host they infect. Animal viruses have a more refined classification system that goes as high as families. The major criteria are type of nucleic acid, presence or absence of an envelope, manner of replication, and morphologic characteristics.<sup>12,13</sup>

Simpler forms of self-replicating organisms include virioids and viroids.<sup>14,15</sup> The former are satellite RNAs that are found encapsidated in the proteins encoded by their helper virus (e.g., hepatitis caused by the hepatitis D virus delta agent in conjunction with hepatitis B virus). The viroids are mostly plant pathogens that consist of single-stranded circular RNA molecules.

The concept of “infectious agent” has been revolutionized by the discovery of proteinaceous infectious agents known as prions. These proteins are responsible for neurodegenerative diseases in animals and humans. The protein particles lack nucleic acids but still are able to reproduce and trigger conformational changes in host proteins, leading to cell death.<sup>16,17</sup>

In contrast, protozoa are nucleated, single-cell organisms that, depending on the species, replicate by means as simple as binary fission (e.g., *Trichomonas*) or as complex as involving multiple sexual and asexual stages in both animal and invertebrate hosts (e.g., malaria). Protozoa include amebae (e.g., *Entamoeba histolytica*), flagellates (e.g., *Giardia lamblia*), ciliates (e.g., *Balantidium coli*), and sporozoa (e.g., *Cryptosporidium*). Even more complex are helminths, which are multicellular metazoan organisms with highly developed internal organs, including alimentary and reproductive tracts. The helminths include nematodes (roundworms), cestodes (tapeworms), and trematodes (flukes). Many helminths have complex life cycles with multiple developmental stages both in the animal host and in intermediate invertebrate or vertebrate hosts. Because of their size, helminths, the macroparasites, are solely extracellular pathogens; because of their prolonged life cycles and generation times, their capacity for genetic alteration is diminished compared to smaller, simpler microbes (the microparasites).

## Development of Microbial Virulence

### Evolution of Virulence

The traditional view assumes that natural selection would favor evolution toward a benign coexistence between host and parasite.<sup>18,19</sup> In other words, virulence was considered an artifact of recent associations between parasites and their hosts. At the logical end, the relationship would become that of commensalism or mutualism. However, this model does not explain epidemiologic observations that in some cases challenge the traditional view. A modern view of evolution

of virulence focuses on the trade-off between the benefits that pathogens accrue through increased exploitation of hosts and the costs that result from any effects of disease that reduce transmission to susceptible hosts.<sup>19,20</sup> From this point of view, virulence could be the evolved as well as the primitive stage of the association between host and parasite, depending on the development of enhanced rather than reduced transmission.

According to Levin<sup>19</sup> and Levin and Svanborg-Eden,<sup>20</sup> there are three alternative models to explain evolution of a micro-parasite's virulence: direct selection, coincidental evolution, and short-sighted within-host selection. The direct selection model states that there is a direct relationship between the parasite's virulence and its rate of infectious transmission. The best documented and often cited example is that of the dramatic changes in virulence that the myxoma virus underwent after being released into the wild in Australia to “control” the population of wild rabbits. In the beginning, rabbit mortality and viral transmission rates were high. As the population of rabbits was decimated, the virulence of the virus decreased and its rate of transmission actually increased. This outcome is explained by the longer survival and duration of the period of shedding of the virus. At the same time, more resistant rabbits increased in number due to the selection process.<sup>21</sup>

According to the coincidental evolution model, the factors responsible for the virulence of a microparasite evolved for some purpose other than to provide the parasite with some advantage within a host or for its transmission to other hosts. Clostridial toxins are good examples in this category. There is no beneficial reason to kill a human host who became infected by *Clostridium tetani* spores from soil in order for the parasite to survive. They are mostly soil bacteria and do not need humans for their survival.<sup>19</sup>

Short-sighted within-host evolution posits that the parasites responsible for the morbidity and mortality of the host are selected for as a consequence of within-host evolution since that produces a local advantage for their survival within the host. The host dies and the rate of transmission would decrease. This is an example of evolutionary myopia in which the long-term consequences of killing a host would not matter to the parasite.<sup>22,23</sup> Natural selection is a local phenomenon that happens at a given time and place and goes perfectly with this model. Bacteria such as *Neisseria meningitidis* that normally live attached to human pharyngeal epithelial cells sometimes invade the central nervous system (CNS) and kill the host. Their replication in the CNS is favored since competition is low and defenses are not as abundant as in the tonsillar areas.<sup>19</sup>

The generation times of mammalian hosts are much longer than those of microorganisms. Therefore, genetic mutations in these hosts, on which natural selection acts, take longer to become part of a large population. Nevertheless, there is evidence that specific microorganisms can exert selective pressure on the gene pool of human hosts. The evidence is strongest for the potentially lethal infections caused by falciparum malaria. In regions of the world where falciparum malaria is endemic, including Africa, there is a high prevalence of genetic mutations that alter hemoglobin structure or synthesis. Falciparum malaria parasites cannot survive in the presence of the mutated forms of hemoglobin, and therefore hosts with specific genetic hemoglobinopathies (the  $\alpha$ - and  $\beta$ -thalassemias and hemoglobins S, C, and E) are spared the lethal consequences of falciparum malaria.<sup>24</sup> The selective

pressure of malaria on human gene expression is not confined solely to affecting erythrocytes but also likely involves the immune system, cytokines, and other systems.<sup>25</sup>

### Other Modes of Altering Virulence and Pathogenicity

Although the selective pressures of evolution generally exert changes over a multitude of centuries, there are other mechanisms that may more rapidly alter microbial pathogenicity, virulence, and drug susceptibility. The expression of mutated genes in microorganisms is heightened when there are greater numbers of organisms and their generation times are brief. Hence, altered gene expression in helminths will be slow to be expressed, whereas in microparasites genetic alterations will be likely to develop. For mycobacterial infections, large numbers of bacilli that persist for a long time facilitate the genetic emergence of drug resistance to a single agent, and this likelihood underlies the principle of using more than a single drug to treat tuberculosis. Even more rapidly dividing microparasites can develop genetic alterations, and this is especially true when the fidelity of genetic replication is poor. This is prominent in human immunodeficiency virus type 1 (HIV-1), whose reverse transcriptase lacks a 3' exonuclease proofreading activity.<sup>26</sup> Alterations in cell tropism, pathogenicity, and drug sensitivity are frequent in HIV-1 infections. Again, several antiviral agents must be employed concomitantly to circumvent the highly frequent mutations that alter drug susceptibility in HIV-1 strains.

In addition to their own genetic material, many classes of microparasites either contain or are capable of acquiring transferable genetic elements in the form of plasmids, transposons, or bacteriophages. Bacterial virulence factors that are encoded by plasmids include the heat-stable and heat-labile enterotoxins of *Escherichia coli*, the toxins of *Shigella* and enteroinvasive *E. coli*, and the neurotoxin of tetanus. Phage-encoded bacterial virulence determinants include diphtheria toxin, botulinum neurotoxin, and the Shiga-like toxins of enterohemorrhagic *E. coli*. These transferable genetic elements also provide a means for the spread of resistance to antibacterial drugs, an increasing problem in all regions of the world.<sup>27</sup>

### Microorganisms and Their Impact on Human Affairs

The overall influence of microorganisms on our daily lives is beneficial. Disease is not the rule with microorganisms, and most of them coexist with the rest of the species in the biosphere without causing any harm to the higher organisms.<sup>1</sup> The beneficial aspects of microbes are innumerable, including innate resistance due to normal flora, antibiotic production, utilization in the dairy and biotechnology industries, enhancement of plant survival due to nitrogen-fixing bacteria, production of natural gas by methanogenic bacteria, and the degradation of crude oil.<sup>1</sup> The impact of infectious diseases on humans includes acute or chronic illness of individuals, widespread effects on infected populations, and comorbid influences on nutrition and development.

### Causes of Acute or Chronic Infections in Individuals

One obvious impact of an infectious disease is on the individual infected. Hence, in any region of the world independent

of other infectious diseases or malnutrition, the acute infection will cause morbidity and potential mortality in the infected human host. Among otherwise healthy people, the immediate impact of the infection is the symptomatic acute illness. For some infections that have prolonged courses, their impact may also continue over many years. Chronic infections include most of those caused by helminthic parasites, which characteristically live for years; persisting mycobacterial infections; and retroviral infections (HIV-1, HIV-2, and human T-cell lymphotropic virus type 1). Finally, the sequelae of some infections can include the development of neoplasms. Examples include hepatomas associated with chronic hepatitis B and C viral infections, bladder tumors with urinary schistosomiasis, cholangiocarcinomas with biliary fluke infections, and gastric adenocarcinomas and lymphomas associated with *Helicobacter pylori* infections.

### Causes of Widespread Infections in Populations

Infectious diseases may affect not only individuals but also large groups of people or entire populations due to epidemic or highly endemic transmission. Throughout human history, a few microorganisms have been responsible for great epidemics and massive numbers of dead or crippled people as a result of infections spreading locally or throughout the world.<sup>28–31</sup> Typhus has had a great impact. Typhus has been associated almost always with situations that involve overcrowding, famine, war, natural disasters, and poverty. The outcomes of several European wars were affected by the morbidity and mortality inflicted by typhus or other diseases on the military. Typhus epidemics were common during the world wars of the 20th century and in the concentration camps where the ecological conditions were ideal for such a disease to spread.<sup>30</sup> Today, typhus and other rickettsioses are still public health problems in some countries, but overall the disease was brought under control after its life cycle was described and antibiotics, insecticides, and public health measures became available.<sup>30</sup>

Bubonic plague, caused by *Yersinia pestis*, is another disease that has shaped history, especially in Europe during the Middle Ages.<sup>31</sup> Millions of people were affected by pandemics that spread throughout the continent. Tuberculosis, smallpox, and measles had a tremendous effect on the native populations of the Americas after Columbus's voyages to the New World. It has been estimated that 90% of the population in Mexico was killed by these pathogens, which were novel to the native residents.

Acquired immunodeficiency syndrome (AIDS) represents the modern pandemic that will continue to affect human history for at least decades. Other examples are cholera and influenza, which are capable of causing pandemics.<sup>32</sup>

In addition to widespread disease caused by epidemic spread of infections, some infectious diseases, because of their highly endemic prevalence in populations, continue to affect large segments of the world's population. These include enteric and respiratory infections, measles, malaria (which still causes 1 to 2 million deaths per year, especially on the African continent), and tuberculosis (which has become the number one killer in the world). Schistosomiasis is an important disease, affecting more than 200 million people worldwide. Furthermore, even the staggering mortality and morbidity of these tropical

infectious diseases do not control populations but are associated with population overgrowth. This is true not only across the different countries of the world but also throughout the history of developed countries. Thus, the impact of these infections is not solely on the individual but, because of their highly endemic or epidemic occurrence, on populations. This has consequences on economic, political, and social functioning of entire societies.<sup>33</sup>

### Polyparasitism and Effects on Nutrition and Growth

In an otherwise healthy and fully nourished person, a new infection is likely to be the only active infection in that person. In contrast, in regions where enteric and other infections are highly prevalent because of inadequate sanitation and poor socioeconomic conditions, adults and especially children may harbor several infections or be subject to repeated episodes of new enteric pathogens. Thus, the polyparasitism of multiple concurrent or recurrent infections adds a new dimension to the impact of acute infections, not often encountered in developed countries.

Moreover, the subclinical impact of a number of tropical infectious diseases is beginning to become apparent. Increasing data suggest that even “asymptomatic” giardial,<sup>34</sup> cryptosporidial,<sup>35</sup> and enteroaggregative *E. coli*<sup>36</sup> infections may be very important in predisposing to malnutrition, thus reflecting a clinically important impact, even in the absence of overt clinical disease such as diarrhea. Likewise, chronic intestinal helminth infections also have a major impact on nutrition in those with already marginal nutrition. Anthelmintic therapy in these children, who lack symptomatic infections, has led to increases in growth, exercise tolerance, and scholastic performance.<sup>37,38</sup>

### Principles of Microbial Metabolism

Microbes are present in every ecosystem of the planet. Therefore, their metabolic pathways are as varied as their ecosystems. Based on the source of energy, they are subdivided into phototrophs (light-derived energy), lithotrophs (inorganic compound-derived energy), and heterotrophs (organic compound-derived energy). Based on the carbon source, microorganisms are either autotrophs (inorganic carbon) or heterotrophs (organic carbon).<sup>1,7</sup> In order to obtain energy from nutrients, organisms need to oxidize food and pass electrons through a chain of electron transporters until they are finally accepted by an oxidizing substance such as oxygen. Some bacteria evolved well before oxygen was present in the earth's atmosphere, and they still use electron acceptors other than

oxygen (e.g.,  $H_2S$  and  $NO_3$ ). These are anaerobes, and they range from obligate anaerobes to aerotolerant, microaerophilic, and facultative organisms. Most human pathogens are heterotrophs and range from strict anaerobes to obligate aerobes in regard to utilization of oxygen as the final electron acceptor.

### MICROBIAL INTERACTIONS WITH HUMAN HOSTS

Just as microorganisms have evolved over centuries or longer, mammalian hosts have evolved to contain and limit the deleterious consequences of infections with diverse microbes. The human immune system is composed of multiple elements, including those of innate immunity and those of adaptive immunity. Many of the elements of innate immunity are more primitive and found in invertebrate organisms, whereas the adaptive immune responses have evolved further in vertebrate hosts. Microorganisms that successfully infect human hosts must, at least in the short term, overcome elements of the host immune system, which then may react further to attempt to control these infections.

Microorganisms that infect humans are exogenous to the host and must colonize or penetrate epithelial barriers to gain access to the host. Except for infections acquired during the intrauterine period, infectious agents must bridge host epithelial surfaces, the keratinized epithelium of the skin, or the mucosal epithelium of the respiratory, gastrointestinal, or genitourinary tracts. Ultimately, there are four types of microbial localization in the host (Fig. 1-1). Some microbes will enter intracellular sites either within the cytoplasm or within vesicular or vacuolar compartments in cells. Other microbes remain extracellular, either at epithelial surfaces or within the host in the blood, lymph, or tissues.

### Interactions at Epithelial Barrier Surfaces

The barrier functions occurring at epithelial surfaces are part of the innate host defenses and are important in determining the outcome of interactions of potential pathogens with the host. Interactions at epithelial barriers involved in defense against external microbes include not only the physical properties of the epithelial surfaces but also the overlying mucous phase, the ciliated or other propulsive activities facilitating microbe clearance, and the normal microbial flora.

### Normal Flora

Vertebrate warm-blooded organisms, such as humans, are an ideal site for the survival of many microbes and provide

FIGURE 1-1 Microbial localization.

a rich source of organic material and a constant temperature and pH. Microbes coexist with us in and on our bodies, especially on epithelial surfaces where there is contact with the outside world, such as the bowel, upper respiratory tract, mouth, skin, and distal portions of the genitourinary tract.<sup>1,2,39</sup> Most of these microorganisms are highly adapted to live with us and do not cause any harm. The presence of the same type of microorganisms at a particular site in the absence of disease is called colonization. Normal colonizing microbial flora help to limit access by potentially pathogenic microorganisms. One condition predisposing to infection is the alteration of the normal epithelial flora, as occurs with antibiotic therapy, since this may allow for the proliferation of pathogenic organisms normally held in balance by the endogenous normal microbial flora. Examples include *Candida* vaginitis or the development of pseudomembranous colitis due to toxigenic *Clostridium difficile*, which may complicate antibiotic therapy.

### Adhesion to the Epithelium

Microorganisms maintain themselves in or on their host by adhesion to cells or the extracellular matrix. Adhesins are encoded by chromosomal genes, plasmids, or phages.<sup>40</sup> They are usually divided into fimbrial and afimbrial adhesins.<sup>41</sup> Fimbrial adhesins are present in organisms such as *Neisseria gonorrhoeae* and are in part responsible for the attachment to genitourinary tract epithelium, preventing the bacteria from being washed out by the urine stream.<sup>42</sup> An example of an afimbrial adhesin is the filamentous hemagglutinin of *Bordetella pertussis*, which is responsible for the attachment of *B. pertussis* to epithelial cells in the respiratory tract.<sup>43</sup> Adhesins attach to receptors in the host. These receptors include proteins, glycolipids, and carbohydrates exposed on the surface of cells or in the extracellular matrix.<sup>40</sup> Integrins are one class of proteins present on eukaryotic cell surfaces that can serve as bacterial receptors.<sup>40</sup> *Helicobacter pylori* binds to Lewis blood group antigen present in the gastric epithelium.<sup>44</sup> *Neisseria* has a ligand that binds to CD66 molecules on epithelial cells.

Some pathogens have even more evolved interactions with the host and activate signal transduction mechanisms in the host cell, which in turn upregulate other molecules that aid in the adhesion process.<sup>2,40</sup> Certain strains of enteropathogenic *E. coli* possess type III secretion or contact-mediated systems.<sup>45</sup> In such cases, the secretion and synthesis of virulence factors is modulated by contact with host surfaces. The systems are complex (more than 20 genes are involved) and have not been elucidated completely at the molecular level.<sup>46,47</sup>

### Penetration of the Epithelial Barriers

Some microbes do not have the means to penetrate skin barriers and are only able to gain access through bites produced by arthropods (e.g., rickettsiae, arboviruses, plasmodia, and filariae).<sup>48,49</sup> In such cases, microbes may be introduced by direct inoculation (e.g., rickettsiae, arboviruses, and plasmodia) or may gain access by migrating through the puncture site (filariae). Other microbes (e.g., skin bacteria and fungi) depend on mechanical disruption of the skin (e.g., due to burns, trauma, or intravenous catheters) to invade deeper structures.<sup>50</sup> Still others invade when defenses on mucosal surfaces are lowered due to combined local or generalized

immunosuppression and altered mucosal integrity (mucositis) due to chemotherapy or malnutrition (e.g., *Candida* spp. and anaerobic and other enteric bacteria in the bowel). Some microbes do not invade tissues at all and affect the host locally and systemically by liberating toxins at the site of colonization (e.g., diphtheria exotoxin).<sup>40</sup>

For enteric pathogens, some, including poliovirus, *Salmonella typhimurium*, *Salmonella typhi*, *Campylobacter jejuni*, *Yersinia enterocolitica*, and *Yersinia pseudotuberculosis*, gain access to the host across the intestinal epithelium by utilizing uptake in specialized epithelial M cells.<sup>51</sup> Internalization of some microorganisms is also achieved through other mechanisms, such as sequential “zipper-like” encircling of the organisms triggered by bacterial ligands and cellular receptors, as occurs in infections caused by *Listeria monocytogenes*.<sup>40</sup> The trigger mechanism of the bacteria induces massive rearrangements of cytoskeletal proteins such as actin, which results in membrane ruffles, as occurs with shigellosis and salmonellosis.<sup>40</sup>

In the genitourinary tract, invasion of some microbes (e.g., HIV-1) is facilitated by mucosal erosions caused by other infectious agents.<sup>52</sup>

### Spread from the Portal of Entry

Once the organisms gain access to the body after overcoming the first lines of defense, they either spread to other sites of the body or reproduce locally and often invade surrounding tissues. Local spread is facilitated by a number of factors, including collagenases, hyaluronidases, fibrinolysis, and other enzymes. They are produced by a wide range of organisms, and the role of these enzymes in invasion is, in some cases, controversial.<sup>2</sup>

Lymphatic spread occurs in most cases once the organisms gain access to subepithelial tissues or serosal surfaces. Lymphatic vessels are distributed in most tissues of the body, with few exceptions such as the brain. Lymph is carried by lymphatic vessels to regional lymph nodes, where it circulates through the node and eventually returns to the systemic circulation through the thoracic duct and the great lymphatic vein. One to three liters of lymph is returned to the systemic circulation every day. Most pathogens are filtered in lymph nodes before reaching the systemic circulation, but some actually reproduce either in the endothelium of lymphatic vessels (e.g., *Mycobacterium leprae*)<sup>2,53</sup> or in tissue macrophages present in the lymph nodes (e.g., *Y. pestis* and *Brucella* spp.) or lymphocytes (HIV and herpesviruses, including Epstein–Barr virus).<sup>54</sup> Some organisms reach the systemic circulation after overwhelming the defenses in the lymph nodes (e.g., *Bacillus anthracis* and *Y. pestis*).

Microorganisms carried in the blood are transported either extracellularly (e.g., most of those causing bacteremia) or intracellularly. Intracellular pathogens are carried by red blood cells (e.g., *Plasmodium*, *Babesia*, Colorado tick fever virus, and *Bartonella*), monocytes (e.g., measles virus, cytomegalovirus, and *Toxoplasma*), or neutrophils (e.g., *Anaplasma phagocytophilum*, *Ehrlichia ewingii*, and some pyogenic bacteria).<sup>2,55</sup>

Once in the blood, by initial lymphatic or hematogenous spread, the microorganisms have access to virtually any site in the body. However, some pathogens exhibit tropism for certain tissues. This tropism depends on multiple factors, including the anatomy of the microcirculation in a given tissue (fenestrated

capillaries vs continuous endothelial lining), receptors present on certain endothelial cells, and the presence of mononuclear phagocytic cells in organs such as bone marrow, liver, and spleen.<sup>2</sup> Other less common routes of spread include peripheral nerves (e.g., rabies and varicella-zoster virus), cerebrospinal fluid (after the organisms traverse the blood–brain barrier), and serosal cavities.

## Localization in the Host

Microbes that have gained access to the host at or through epithelial barriers then, depending on the properties and size of the pathogens, either have the capacity to seek intracellular sites or remain extracellular (see Fig. 1-1). Mechanisms of host immune responses to the microorganisms vary depending on their sites of localization.

### Intracellular Localization

Specific microorganisms use highly developed processes to gain access to and survive within host cells. The microorganisms may be either in the cytoplasm or within vesicular or vacuolar compartments of targeted cells.

Targeting and penetration of cells is governed by the interactions of microbial surface proteins that may engage host cell molecules that function as receptors for the microbial ligands. The entry of malarial parasites into erythrocytes is a good example, and the nature of the erythrocyte receptors used by different malarial parasite species governs which red blood cells are infected. *Plasmodium vivax* binds to the Duffy blood group antigens present on some people's red blood cell membranes. The expression of the Duffy blood group antigen is genetically determined, and this antigen is present mostly in whites and Asians and largely absent in blacks of sub-Saharan African ancestry.<sup>56–59</sup> This genetic absence of a receptor on red blood cells required for vivax malaria's survival explains why vivax malaria is rare in regions of Africa. *Plasmodium vivax* also exhibits a characteristic restriction in the age of erythrocytes it infects. Only young red blood cells and reticulocytes are susceptible to infection, even though the Duffy blood group antigen is present on red blood cells of all ages. The basis for this restriction to younger red blood cells also rests with receptor-mediated limitations. *Plasmodium vivax* parasites contain reticulocyte binding proteins, which recognize and bind to reticulocyte-specific antigens on the red blood cell surface.<sup>60,61</sup> Thus, host cell receptor–microbial ligand interactions have an impact on the geographic range of infections based on host genetic differences in requisite receptor expression and on the specific cells that a microbe may enter.

Another example of the intricacies of microbe-receptor interactions has been recognized with HIV-1. Although CD4 is the primary cellular receptor for HIV entry, binding to CD4 alone is not sufficient for entry of HIV-1 into cells. Cellular coreceptors that are members of the chemokine receptor family of seven-transmembrane G protein–coupled molecules are also important. T-cell tropic strains use the CXCR-4 chemokine receptor and macrophage tropic HIV-1 strains use the CCR-3 and CCR-5 chemokine receptors as coreceptors in concert with CD4. The differences among strains of HIV-1 in their capacities to bind to different chemokine receptor–coreceptors may help explain differences in cell tropism and

pathogenicity, the lack of infectability of nonprimate cells, and, for those with genetically altered coreceptors, the apparent resistance to HIV-1 infection of some individuals.<sup>62–65</sup>

Typical of those etiologic agents that have an intracellular localization are viruses. The entry of these agents into cells is increasingly recognized to be dependent on their interactions with specific host cell proteins that act as their “receptors.” For instance, host cell molecules that function as viral receptors include multiple isoforms of membrane cofactor protein (CD46), a complement regulatory protein, for measles; the integrin, intracellular adhesion molecule-1 (ICAM-1), for rhinovirus; erythrocyte P antigen for parvovirus B19; and the C3d complement receptor (CR2) for Epstein–Barr virus.<sup>66–69</sup>

Microbes that exist principally within the cytoplasm are sequestered from many immune response mechanisms active on extracellular pathogens, including antibody and phagocytic cells. Viral intracellular proteins will be processed and displayed with class I major histocompatibility complex (MHC) proteins, which enable CD8 cytotoxic T cells to recognize and kill the virally infected cell.

Other microbes are internalized within phagocytic cells, especially macrophages. Once internalized in host cells, organisms such as *Salmonella*, *Mycobacterium*, *Chlamydia*, and *Legionella* use an extraordinary assortment of mechanisms to prevent their phagocytic vacuole from fusing with the host cells' acidifying lysosomes.<sup>70–72</sup> For some parasites, the intracellular environment is an important determinant of parasitism. For example, *Leishmania* and *Coxiella* (unlike other pathogens) benefit from the acidic environment of the macrophage phagolysosome. *Leishmania* use the proton gradient across the lysosome to drive the energy-dependent uptake of two important substrates: glucose and proline.<sup>73</sup> Thus, *Leishmania* amastigotes actually survive in the macrophage phagolysosome because they benefit from its proton gradient and because they avoid activating the processes that normally kill ingested microorganisms. Leishmanial lipophosphoglycan inhibits the action of  $\beta$ -galactosidase, chelates calcium, inhibits protein kinase C and the oxidative burst, and may scavenge toxic oxygen metabolites.<sup>74</sup>

Conversely, other intracellular pathogens such as *Toxoplasma gondii* survive within the macrophage by using an alternative pathway of entry that avoids fusion of the parasitophorous vacuole with lysosomes.<sup>71,75</sup> In contrast, dead or antibody-coated *T. gondii* enter via the Fc receptor and are routed to a different intracellular compartment, which fuses with the lysosome, and are then killed in the phagolysosome.<sup>71,76</sup>

Other organisms, such as *Shigella*, *Listeria*, and *Rickettsia*, breach their vacuolar membrane to multiply freely in the cytoplasm and may also usurp host cellular actin to propel their further spread to neighboring cells, continuing to exploit their intracellular sanctuary.<sup>77–79</sup>

Immune responses against microbes within macrophages rely heavily on class II MHC-mediated presentation of host antigenic peptides to T helper 1 (Th1) types of CD4+ T cells, which then augment the microbicidal activities of the macrophages.

### Extracellular Localization

Some types of microbes that remain extracellular typically reside at epithelial surfaces, including bacteria such as *N. gonorrhoeae*, *H. pylori*, *Vibrio cholerae*, and *E. coli*, and

helminths such as adult *Ascaris lumbricoides*, hookworms, and *Trichuris trichiura*. Mucosal immune responses, including IgA and leukocytes, participate in host immune reactions to these pathogens.

Other microbes that survive extracellularly are present within the blood, lymph, or tissues of the host, and these organisms include fungi, viruses, bacteria, protozoa, and notably the helminths. Multicellular helminths, due to their large size, remain forever extracellularly and may be found in the blood (e.g., microfilariæ), lymph (adult lymphatic filarial worms), tissues (migrating larvae and adult stages of some helminths), and cerebrospinal fluid. Host defense against extracellular pathogens uses antibodies, complement, phagocytic cells, and, for helminths, IgE, eosinophils, and mast cells.<sup>80</sup>

## Tissue Damage

There are multiple mechanisms by which microbes inflict damage on host tissues.

### Direct Damage or Alteration of Host Cell Function

Host cells can be killed directly by the infectious agent, as in some viral or bacterial infections that are highly cytopathic (e.g., yellow fever virus in hepatocytes and *Salmonella* in macrophages).<sup>81,82</sup> Some microorganisms multiply intracellularly until the cell bursts and dies (e.g., *Rickettsia prowazekii*).<sup>30</sup> Some bacteria, viruses, and other parasites, such as *Shigella*, HIV-1, and *Listeria*, can induce apoptosis of host cells.<sup>54,83,84</sup> Apoptosis is triggered by different mechanisms, such as activation of the interleukin-converting enzyme (ICE) pathway.<sup>85,86</sup> This form of programmed cell death is probably more widespread as a mechanism of cell death in infectious diseases than previously thought.

Damage is sometimes caused by toxins secreted by bacterial cells (exotoxins). In this case, bacteria can either invade host tissues or colonize mucosal sites and then release toxins at the mucosal site that are absorbed systemically and cause distant damage.<sup>87</sup> Exotoxins can act through different pathways that damage the components of the cell membranes such as phospholipids<sup>88</sup> or affect signaling pathways (e.g., *V. cholerae*).<sup>40,89</sup> Other exotoxins, such as streptolysins and listeriolysins, alter membrane permeability. Still others, such as exfoliatin (e.g., *Staphylococcus aureus*) and elastase (e.g., *Pseudomonas* spp.), are capable of degrading extracellular elements.<sup>2</sup> Some toxins are translocated to the intracellular environment, where they affect multiple enzymatic systems. These toxins are classified according to their enzymatic activity, such as adenosine diphosphate (ADP) ribosyl transferase (e.g., diphtheria toxin, *P. aeruginosa* exotoxin A, and pertussis toxin), depurinase (e.g., Shiga toxin), adenylate cyclase (e.g., pertussis hemolysin and anthrax edema factor), and zinc protease (e.g., tetanus).<sup>89</sup> The end result ranges from blockade of protein synthesis and cell death or blockade of exocytosis (especially CNS neurotransmitters at the synaptic cleft)<sup>90,91</sup> to increases of cyclic adenosine monophosphate (AMP) or cyclic guanosine monophosphate (GMP) and changes in cell permeability.<sup>89</sup> Still other organisms, such as *C. difficile*, produce toxins that change basic cell signaling transducers such as Rho to alter cell function or affect their spread. Finally, organisms can interact with host cell or microbial transcriptional regulation of genes (such as

iron binding proteins for uropathogenic *E. coli*<sup>87,92</sup>) or cytokine release (such as *H. pylori* or enteroaggregative *E. coli*<sup>36,93–95</sup>) to enhance their survival or elicit pathogenic responses. The evolutionary advantages to a microbe of its remarkable array of traits we call “virulence” hold many of the clues to their control, if we can but truly understand them.

Endotoxins are a subset of lipopolysaccharides present in the outer membrane of gram-negative bacteria that can trigger a wide variety of responses in the host, including massive cytokine release leading to hypotension and shock.<sup>96,97</sup> These deleterious effects occur with high-grade invasion of the blood by gram-negative bacteria, including enteric gram-negative bacteremias and meningococcemia.

### Indirect Damage

Damage to the host may also develop as a consequence of immune reactions to the infectious agents. One scheme for classifying immunopathologic responses divides the reactions into four types based on the elements of the immune response involved.<sup>98</sup>

Type I reactions involve elements of strong Th2 responses that lead to increased IgE, eosinophilia, and eosinophil and mast cell activation. Adverse reactions of this type include the development of urticaria (with several helminthic parasites), the occurrence of potentially life-threatening anaphylactic shock in IgE-mediated mast cell degranulation (e.g., triggered by systemic release of antigens from echinococcal cysts<sup>99</sup>), and exuberant eosinophilic infiltration of tissues due to migrating helminth larvae (e.g., Löfller's pneumonia with the pulmonary migration of *Ascaris* larvae).

Type II reactions are also dependent on elements of Th2 cell responses that lead to increased IgM and then IgG antibodies directed toward the infectious agents. These antibodies, if cross-reactive with host antigens, may lead to complement-mediated cytotoxicity or antibody-dependent cell-mediated cytotoxicity by natural killer cells, which have Fc receptors. An example of this type of immunopathologic response is the uncommon hemolytic anemia associated with *Mycoplasma pneumoniae* infection that is mediated by complement-induced hemolysis triggered by IgM (cold agglutinin) antibodies against erythrocyte I antigen.

Type III reactions are caused by the deposition of immune complexes. When neither antibody nor antigen is present in excess of one another, the complexing of antibodies with soluble antigen results in the formation of immune complexes that may cause disease. This may develop acutely as antibody titers rise in the presence of microbial antigens, causing the syndrome of serum sickness. In addition, when soluble antigen is persistently abundant, sustained formation of immune complexes develops, leading to chronic immune complex-mediated tissue damage (especially glomerulonephritis), as found in subacute bacterial endocarditis, chronic hepatitis B antigenemia, and chronic *Plasmodium malariae* infections.<sup>100</sup>

Type IV reactions include adverse reactions mediated by macrophages and cytotoxic T cells. Examples are damage caused by granulomas in leprosy, tuberculosis, tertiary syphilis, and fungal infections. Likewise, granulomas developing around schistosomal eggs, depending on their location, may cause ureteral obstruction or hepatic presinusoidal lesions. Other deleterious inflammatory reactions in this category are

mediated by parasite-elicited host cytokines, such as the hepatic fibrosis elicited by schistosomal eggs.

## IMMUNE INTERACTIONS

### Immune Evasion

The human immune system has evolved in concert with microbes and is very sophisticated, especially with regard to host defenses against microbes, but the system is not perfect. Interactions of the immune system with microbes are an ongoing affair. Microbes have a high mutation rate compared to human beings. Microbes have evolved a diversity of mechanisms that can enable microorganisms to subvert immediate immunologically mediated elimination. Persistence within the host is necessary for the propagation of some parasites.

There are multiple mechanisms by which microbes can persist in the body and evade the immune system. *Tolerance* is defined as specific reduction in the response of the immune system to a given antigen.<sup>101,102</sup> In the case of transplacental infection, the fetus develops a certain degree of tolerance to antigens to which it is exposed. The immune system of fetuses is rather incompletely developed in utero, and microorganisms survive easily. Cytomegalovirus infects the fetus transplacentally and produces extensive damage to multiple tissues. After delivery, infants continue shedding virions for weeks to months because they are unable to destroy the virus. Other mechanisms include the production of superantigens that stimulate a large population of T cells, which then become deleted if the encounter occurs during early development. Exposure to massive amounts of antigen in the circulation can also lead to tolerance.<sup>2,98</sup> Immunosuppression is a well-demonstrated phenomenon that occurs during certain infections caused by viruses, bacteria, protozoa, and helminths. These infections usually involve the lymphoid tissues and macrophages and hamper the immune response.

Intracellular pathogens that are able to spread from cell to cell without exposure to the extracellular compartment can avoid exposure to some elements of the immune system. In other cases, pathogens reside in sites relatively inaccessible to the immune system, such as glandular luminal spaces or kidney tubules. In many infections, antibodies are produced but do not effect microbial killing. Sometimes, antibody avidity is low, the epitopes against which the antibody is directed are not critical to the microorganism's survival, or the mechanism of immune elimination is not antibody dependent.<sup>2</sup>

Other microorganisms have developed means of counteracting specific elements of immune responses, such as production of an IgA-degrading enzyme, IgAase, by certain strains of *N. gonorrhoeae*.<sup>103</sup> Some strains of amoebae also produce proteases that destroy complement.<sup>2</sup> Reactivation of infections in old age due to waning immunity has been well demonstrated in cases of tuberculosis and varicella-zoster virus, allowing transmission to new hosts.

One well-studied mechanism of immune evasion is the capability of changing the antigenic structure by genetic mutation or by programmed sequential expression of genes encoding different surface antigens.<sup>104</sup> Antigenic drift and recombination between influenzaviruses affecting humans

and animals are well documented. *Borrelia recurrentis* and *Trypanosoma gambiense* are also capable of changing their surface antigens after antibodies control the initial blood-stream infection.<sup>105,106</sup> The new antigens are not recognized by the antibodies, allowing relapse of the infection. Parasites in which sexual reproduction is possible benefit enormously.<sup>107</sup> Genetic variability introduced by crossing over during meiotic divisions is much greater than the variability introduced by asexual reproduction. As many as four crossovers on a single pair of chromosomes have been demonstrated in *P. falciparum*.<sup>108</sup>

Microparasites also have multiple mechanisms by which they can evade the initial line of defense provided by phagocytes. These strategies include killing of the phagocyte (e.g., *Streptococcus pyogenes* and *Entamoeba histolytica*), inhibition of chemotaxis (e.g., *Clostridium perfringens*), decreased internalization of microbes by phagocytic cells (e.g., *T. gondii*), inhibition of opsonins (e.g., *Treponema pallidum*), inhibition of phagolysosome fusion (e.g., *M. leprae* and *Mycobacterium tuberculosis*), and escape from the phagosome into the cytoplasm (e.g., *Rickettsia* spp., *Trypanosoma cruzi*, and *Listeria*).<sup>2,40,70,87</sup> With cell-to-cell spread, microorganisms may be minimally exposed to complement, antibodies, or phagocytes in the extracellular or intravascular spaces.<sup>77,78</sup> Rickettsial infections spread from cell to cell throughout the infected foci in the endothelial layer of the microvasculature.<sup>77,78,89</sup>

Macroparasites, the helminths, have evolved diverse mechanisms that enable them to survive in vivo.<sup>80</sup> Characteristically, helminths live for months to years in infected hosts within the lumen of the bowel, within tissues, or in the blood or lymphatic vessels. Many helminths are in intimate and recurring contact with all elements of the immune system. As a consequence of their size, helminthic worms do not use intracellular mechanisms to evade immune responses but have evolved a number of capabilities that permit their survival. For instance, interference with antigen processing has been well documented in animal models and patients infected with the filarial nematodes *Brugia malayi* and *Onchocerca volvulus*. These helminths produce a family of proteins called the cystatins that are capable of inhibiting proteases responsible for antigen degradation and subsequent presentation through MHC class II pathways in antigen-presenting cells. These proteins are also capable of modulating T cell proliferation and elicit upregulation of IL-10 expression. Other modulators include helminthic derivatives of arachidonic acid such as lipoxin A4, which is capable of blocking production of IL-12 in dendritic cells. Helminthic prostaglandins can also inhibit IL-12 production by dendritic cells. Since helminths have very complex genomes (~21,000 protein encoding genes in some of them), they are capable of producing a large variety of proteins. Some of them are cytokines and related proteins also capable of modulating the host immune response to their advantage. For example, *B. malayi* has been shown to express transforming growth factor (TGF)- $\beta$ -like proteins capable of binding TGF- $\beta$  human receptors. Other cytokines include macrophage-migration inhibition factors produced by several nematodes including *B. malayi*. Blockade of effector mechanisms has also been demonstrated in some helminth infections, including proteases that target effector molecules such as eotaxin. Neutrophil proteases can also be inhibited by serpins.

## THE EFFECTS OF INFECTIONS ON POPULATIONS

Epidemiology is the study of diseases in populations. Pathogens exist in nature because they reproduce and spread to new hosts. One of the main purposes of epidemiology is the study of how the infectious agent is maintained in nature so that adequate measures can be taken to control the disease.<sup>1,2,109</sup>

### Principles of Transmission

The transfer of pathogens in communities involves shedding or excretion of the infectious agent from the host and travel to and entry into a susceptible host. Some organisms are extremely sensitive to environmental conditions such as drying or exposure to sunlight and require close contact between hosts to survive transmission (e.g., *Mycoplasma* spp.). Others are more resistant and can travel to a susceptible host by fomites (e.g., towels, doorknobs, toys, and gloves), vehicles (e.g., food or water), or vectors (e.g., vertebrate animals and arthropods). Transmission of particular diseases can be suspected on the basis of age-specific incidence, geographic and seasonal patterns, and other demographic characteristics. For example, diseases limited to a certain geographic area and season suggest the presence of a vector in the life cycle that determines transmission in that particular region.<sup>1,110</sup>

The way epidemics spread through communities gives some clues to the manner of transmission of an infectious agent.<sup>1,109</sup> Food-borne epidemics are usually explosive, peak in a few days to weeks, and wane abruptly. A large segment of the population is exposed to a common source of infection. In outbreaks involving person-to-person transmission, the number of cases increases slowly, and the disease affects a certain number of susceptible people until it reaches a communicable threshold, after which the number of cases increases slightly faster. If populations are small, the organism dies out before spreading to large segments of the community; that is, a highly communicable stage is never reached.

Other important concepts are those of horizontal and vertical transmission. Horizontal transmission refers to spread of infection from individual to individual in a given population. In contrast, vertical transmission refers to spread of infectious agents from parent to offspring. The latter is important for the maintenance of some arboviruses and rickettsial organisms in their arthropod hosts. They are transmitted transovarially from the female arthropod vector to its offspring. Human pathogens, such as *T. pallidum*, cytomegalovirus, hepatitis B virus, and HIV-1, are also transmitted vertically.

Herd immunity is another important epidemiologic concept. Herd immunity refers to the resistance of a population to a particular disease as a group. For this to occur, a critical proportion of the population must be immune to the pathogen, and once that critical number is reached the rest of the population is protected against the disease. The critical proportion depends on the pathogen and is greater for highly infectious pathogens with long incubation periods and lower for less transmissible pathogens with short incubation periods. For smallpox, the required proportion for herd immunity is approximately 95% and for polio it is 70%. Some diseases have temporal cycles and appear every few years due to variations in herd immunity.<sup>1,28,109,110</sup>

## Principles of Nosocomial Infections

These are infections acquired in hospitals and are associated with multiple factors, including immunosuppression (either iatrogenic or due to disease), the presence of infected or colonized patients nearby, transmission by personnel from patient to patient (as fomites or as carriers), invasive procedures that bypass host defense barriers, and the high frequency of antibiotic resistance in the hospital environment. These diseases usually have a more serious outcome than diseases occurring in the community. Some of the etiologic agents are *Pseudomonas aeruginosa*, nearly all Enterobacteriaceae, *C. difficile*, *Enterococcus*, and *S. aureus*.

### Principles of Control of Infectious Disease Outbreaks

Control measures can focus on reservoirs (slaughter of infected animals and vaccination). Some pathogens have a human reservoir, and control measures are not as simple and require effective treatment, vaccines, or difficult behavioral changes.<sup>1,110</sup> One safeguard against transmission is keeping water and food supplies free of pathogens. Immunization plays an extremely important role in a relatively few diseases, and herd immunity principles apply. For some diseases, immunity wanes with age, and the adult population becomes susceptible again. Quarantine and isolation are also powerful tools. Quarantine is still used by mutual international agreements for a few diseases (plague, cholera, yellow fever, typhoid fever, and louse-borne relapsing fever). Smallpox was quarantinable before its eradication in the 1970s. Isolation of individual patients is usually applied in hospitals where epidemics of highly resistant and highly transmissible organisms are prone to occur.<sup>111</sup>

### Emerging Infectious Diseases

The concept of emerging infectious diseases is not new but has been the focus of attention due to the resurgence of old infectious diseases that were thought to be controlled and the recognition of new pathogens as humans increase their interaction with the biosphere. By definition, an emerging infectious disease is one that has newly appeared in the population or has existed but is rapidly increasing in incidence or geographic range.<sup>112</sup> The list is growing continuously, but the best examples include a wide variety of hemorrhagic fevers and other syndromes caused by viruses such as dengue, arenaviruses, filoviruses, and hantaviruses. Other emerging infections include HIV, cholera with its cyclic pandemics, malaria, yellow fever, cryptosporidiosis, rickettsiosis, ehrlichiosis, and Lyme borreliosis. The factors involved in the emergence or reemergence of infectious diseases are complex and include ecological changes (deforestation, reforestation, flooding, and climatic changes), changes in human demographics and behavior (sexual, cultural, and war), increased international travel, technological advances (organ transplantation and antibiotics), microbial evolution with the appearance of antibiotic-resistant or antigenically distinct strains, and deficiencies in surveillance and public health policy.<sup>108,113–115</sup> The classic triad of microbe, host, and environment is again exemplified.

## TROPICAL INFECTIOUS DISEASES

Globally, as assessed in terms of disability-adjusted life years (DALYs), which measures morbidity and mortality,<sup>111</sup> infectious diseases in 1990 accounted for 36.4% of total DALYs. Infectious disease DALYs were considerably in excess of those attributable to cancer (5.9%), heart disease (3.1%), cerebrovascular disease (3.2%), or chronic lung disease (3.5%).<sup>116</sup>

However, these calculations admittedly miss the disproportionate impact of tropical infectious diseases on the still exploding populations living in impoverished, tropical areas, and they grossly underestimate the major developmental impact of common childhood enteric, helminthic, and other infections.<sup>34,117–119</sup> For those caring for individual patients with infectious diseases, appropriate diagnosis and treatment are important considerations for the individual. Even more important is the consideration of approaches that will lead to diminished acquisition of infectious diseases. For some infectious agents, immunization holds promise, as witnessed by the successful global eradication of smallpox and the potential eradication of poliomyelitis. Greater progress in the control of infectious diseases, however, rests with improvements related to socioeconomic conditions of the population at risk. In developed countries, tuberculosis was diminished well before the introduction of the first antimicrobial agents active against *M. tuberculosis* and was attributable to improved socioeconomic conditions. For the major infectious diseases of the tropics, improvements in sanitation, living conditions, and general public health will be critical in helping control the impact of the diverse infectious agents that currently contribute to human morbidity and mortality. The impact of these infections is related not only to their effect on the health of the infected individual but also to their contribution to the morbidity associated with malnutrition and to their larger societal impact as an impediment to the full development of the political, economic, and social potential of entire populations.

## Factors Influencing Geographic Distribution and Incidence of Tropical Infectious Diseases

H. H. SHUGART  
ROBERT E. SHOPE

### INTRODUCTION

The distribution and incidence of tropical infectious diseases is directly related to geography, evolution, climate, and human factors. The early medical geographers recognized the relationships but were at best only able to document occurrence. Between 1883 and 1886, August Hirsch published in German the second edition of his *Handbook of Geographical and Historical Pathology*.<sup>1</sup> He described in detail the distribution and seasonality of dengue, malaria, smallpox, yellow fever, cholera, plague, typhus, and typhoid fever. He documented the pandemics of cholera, the paradoxical absence of yellow fever from Asia, and the endemicity of dengue and yellow fever in the tropical coastal cities with summer spread to the temperate zone.

A more recent geographer, Jacques May,<sup>2</sup> wrote in the 1950s about the effect of climate and geography on the distribution of malaria, cholera, and other tropical diseases. He traced the origin and travels of cholera, and he related these to the prevailing weather patterns. The reader is referred to at least two other books<sup>3,4</sup> that provide comprehensive maps and discussions of the distribution of tropical infectious diseases.

This chapter builds on the observations and concepts of Hirsch and May. It is not intended to describe the specific distribution of each of the tropical infectious diseases; specific disease chapters of this book do that. Rather, it emphasizes the many natural and human factors, including especially ecology, climate, and human intervention, that influence geographic distribution of agents and diseases and the concepts that govern where and when these diseases appear.

### TRACKING AGENTS WITH MOLECULAR EPIDEMIOLOGIC METHODS

In the past, our ability to determine disease distribution and movement was often hindered by inaccurate diagnosis.

For instance, clinical signs and symptoms are notoriously insufficient in distinguishing causes of fever, diarrhea, or hemorrhagic disease. The advent of reliable laboratory methods helped to confirm clinical diagnosis. In the past decade, molecular technology has matured so that not only can one map the distribution of the agent and disease but also one can determine the genetic composition of agents by methods employing polymerase chain reaction (PCR) and use this genetic information to map the distribution of geographic variants and track the transport of agents from one geographic site to another.

The newly acquired genetic information also helps us understand how agents evolve focally with their reservoirs. Even agents that are widely distributed, such as those causing rabies, poliomyelitis, dengue, cholera, and acquired immunodeficiency syndrome (AIDS), have regional geographic variation so that the transport and introduction of infection into new areas can be tracked using tools such as monoclonal antibodies and PCR.<sup>5-9</sup> The ability to use PCR to detect the presence of disease organisms in food, flowing water, and groundwater<sup>10-11</sup> coupled with automated sampling and analysis equipment and satellite reporting creates the possibility of monitoring very remote sites for disease presence and potential outbreaks.

### ECOLOGY AS A FACTOR IN DISTRIBUTION

Many of the tropical diseases are zoonoses—that is, transmissible in nature from vertebrate animals to humans. The zoonoses are highly sensitive to climatic and other ecological influences. May's classification of infectious diseases<sup>1</sup> has greatly enhanced our conceptual thinking and is fundamental to understanding the basis for the distribution of infectious agents. The term *agent* is used here to mean the infectious entity, including viruses, bacteria, fungi, and parasites. May proposed that agent and number of hosts categorize diseases in the infectious cycle. Two-factor complexes consist of agents transmitted directly from person to person, such as poliovirus. Three-factor complexes involve transmission through a vector or invertebrate intermediate host—that is, a snail, mosquito, or other arthropod. Dengue and malaria, for instance, are transmitted from person to mosquito to person. For the purposes of this chapter, four-factor complexes involve transmission between a nonhuman vertebrate and an arthropod, with humans being usually accidental hosts. Eastern and western encephalitis viruses, for example, are maintained in a reservoir of mosquitoes and birds, with transmission to humans as a spillover from the enzootic cycle.

These cycles have a profound influence on the geographic distribution of the disease agent. An agent transmitted from person to person may persist anywhere that people go and thus have a very wide geographic distribution, affected by human behavior but relatively unaffected by temperature and rainfall. Transmission of a three-factor complex agent is immediately limited geographically by the distribution of the vector or human component of the reservoir. A *reservoir*, as defined by Benenson,<sup>12</sup> is “any person, animal, arthropod, plant, soil, or substance (or combination of these) in which an infectious agent normally lives and multiplies, on which it depends primarily for survival, and where it reproduces itself in such manner that it can be transmitted to a susceptible host.” Note that for some tropical infections, such as vector-borne agents, the reservoir is often a combination of the arthropod

vector and the vertebrate host because the agent depends on both for survival. Transmission of a four-factor complex agent may be even more restricted because geographic and environmental factors limiting distribution of the reservoir (either the vector or the nonhuman vertebrate), as well as human behavior, will limit the distribution of the infectious disease.

### SPECIES DIVERSITY AND FOCALITY IN THE TROPICS

Viruses, parasites, fungi, and bacteria have evolved with their reservoirs from ancestral forms. The evolution of plants and animals in the tropics has generated high species diversity in many taxa. It follows that microorganisms also are diverse in the tropics because each has evolved with specific reservoir hosts. The more diverse the hosts, the more diverse will be the infectious agents. This diversity is also accompanied by focality, an increased degree of spatial localization. Of course, there are exceptions to such focality, namely in birds and bats, which may fly long distances, and human beings, who travel and take along their domestic animals. The microorganisms associated with widely dispersed animals or plants will be less focal.

This focality in the tropics also means that there are probably numerous as yet undescribed agents infecting wild vertebrates and vectors in tropical forests that have the potential to cause disease in people. In 1976, in 1995, and subsequently, Ebola virus emerged from cryptic forest foci in Zaire to cause fatal hemorrhagic human disease. These episodes are a reminder that tropical zoonotic agents may be very focal and hidden in geographically and ecologically limited transmission cycles until people intrude.

Most disease agents are very closely adapted to their vector or vertebrate host. Agents do not easily jump genus and species barriers and thus cannot readily adapt to new environmental conditions when their vector or vertebrate host becomes restricted by a change in environment.

In 1876, Wallace classified and bounded continental and faunal regions.<sup>13</sup> These regions are Nearctic, Neotropical, Palearctic, Ethiopian, Oriental, and Australasian. Theiler and Downs<sup>14</sup> studied the distribution of 280 arboviruses and rodent-associated viruses, and they showed that 247 existed in only one of these regions (Fig. 2-1). Presumably this meant that their vector or vertebrate host was quite specific, and they either were not transported to other regions or there was

no available vector or vertebrate in another region to support their cycle of transmission. Thirty were found in two regions and only three in more than two regions. All but one of the viruses that had been discovered in more than one geographic region infected domestic animals, domiciliary mosquitoes (*Aedes aegypti*), or birds and thus had a means of transportation to another region. Viruses that were adapted to rodents were destined to have a very focal distribution because rodents do not fly and, with the exception of the house mouse and the wharf rat, have limited geographic interchange.

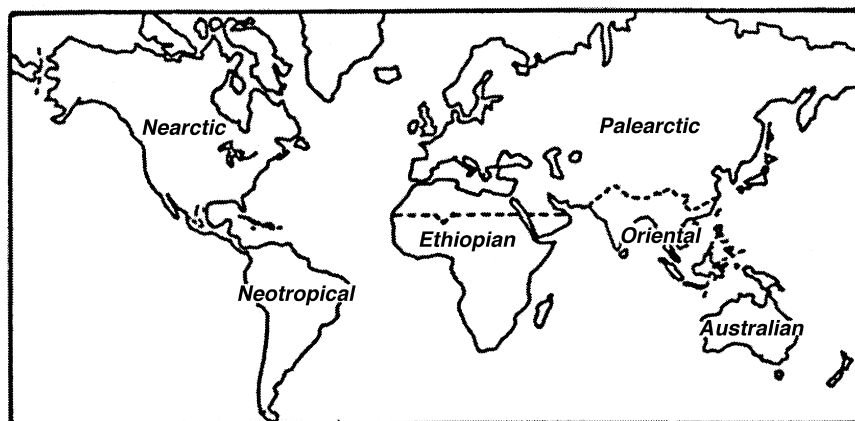

The same concepts hold for most bacterial and parasitic tropical agents that have three- or four-factor complexes. Each of the three major species causing human schistosomiasis, for instance, evolved with a different snail. The distribution of each species is limited to that of the snail: *Schistosoma mansoni* with *Biomphalaria* in tropical Africa and Brazil, *Schistosoma haematobium* with *Bulinus* in Africa and the Middle East, and *Schistosoma japonicum* with *Oncomelania* in the Far East. Although the snail is sometimes more widely dispersed than the schistosome, the potential for disease exists wherever the snail resides. Note also that new areas of disease are being created with the construction of dams that provide ecological conditions to support snails. The schistosomes are subsequently introduced to the dam sites by an influx of human populations that bring the parasite with them.

### CLIMATE AND DISEASE DISTRIBUTION

*Climate* is defined as the customary long-term (usually 30 years) pattern of the weather for any given location. *Weather*, on the other hand, is the short-term state of the atmosphere in regard to temperature, rainfall, humidity, and storms. Temperature is the major governing factor for the distribution of many tropical diseases. Reservoir arthropods, snails, and vertebrates have life cycles that are limited by heat and cold. Many of these creatures do not withstand freezing weather and are thus relegated to the tropics because they do not survive winters in the temperate zones. The distribution of the reservoir therefore determines the limits of distribution of the agent and the disease.

### TEMPERATURE AND AGENTS

Vector-borne infectious agents have a minimum, optimum, and maximum temperature for their replication in the vector.

**FIGURE 2-1** Wallace's (1876) division of the world into faunal regions, modified by Darlington (1957). (From Darlington PJ Jr: Zoogeography. In: The Geographical Distribution of Animals. New York, Wiley, 1957, p 2.)

The time from imbibing an infectious blood meal until the vector is able to transmit to a vertebrate is the extrinsic incubation period. As a general rule, within limits, tropical agents develop more rapidly and to higher infectious titers at warm temperatures than at cold temperatures. Agents such as *Plasmodium*, arboviruses, vector-borne *Rickettsia*, *Borrelia*, *Trypanosoma*, *Leishmania*, and filariae have an extrinsic incubation at near ambient temperature in an arthropod vector. In these infections, the cycle of transmission can usually proceed more rapidly at higher temperatures. The ambient temperature therefore may limit the distribution of these diseases by restricting the amplification of the agent in areas with a short summer season.

### TEMPERATURE AND ARTHROPODS

The temperature also has an effect on the rapidity of development and length of survival of arthropods. Arthropods generally develop more rapidly at warmer temperatures. This means that the eggs hatch earlier, and the passage through life stages is faster, leading in the tropics to early emergence as adults. Warmer temperatures are also usually associated with higher adult arthropod mortality. Immature stages are often less affected by temperature but may not survive extreme cold or heat. The decrease in vector competence attributed to adult mortality may partially compensate for the increase attributed to the more rapid development in the tropics.

The temperature also affects the size of the adult arthropod. Mosquitoes, for instance, are smaller when they develop at warmer temperatures and may therefore require more frequent blood meals. This indirectly makes the smaller mosquito more efficient at transmitting an agent. The aggregate effect of warmer temperatures on arthropods is to increase their efficiency as vectors within broad limits and thus to affect the geographic distribution of the agents they transmit.

### TEMPERATURE AND VERTEBRATES

Many vertebrates can adapt to a wide variation in temperature. Some diseases, however, are restricted in distribution to the tropics because the vertebrate reservoirs cannot withstand freezing weather. One such example is rabies in vampire bats.<sup>15</sup>

### RAINFALL

Rainfall and other sources of water are essential to the presence of many three- and four-factor complex agents. *Aedes aegypti*, for instance, requires water for development, but this may be in the form of rainfall or as stored drinking water in arid areas. Snails that transmit schistosomiasis require water, and this disease often appears in new geographic sites after dams are constructed and irrigation is instituted.

### RAINFALL AND FOOD SUPPLY

The weather may be directly responsible for food or lack of food for the reservoirs of three- and four-factor complex agents. The El Niño or southern oscillation phenomenon has apparently been responsible for periodic increases in wild vertebrate animals such as rodents because of an increase in the food supply following periods of excessive rainfall and warming

in the western United States and along the western coast of South America. The El Niño or southern oscillation is a cyclic change in the ocean currents and the atmosphere that occurs approximately every 3 or 4 years. Prior to the 1993 outbreak of hantavirus pulmonary syndrome in the Four Corners area of the western United States, there was a marked increase in food for the rodents, including pine nuts. There was an associated 10-fold increase in the population of *Peromyscus maniculatus*, the rodent reservoir of Sin Nombre virus. These phenomena have been attributed to an El Niño event<sup>16</sup> and illustrate how weather may influence the distribution and incidence of disease.

### GEOGRAPHIC BARRIERS TO SPREAD OF AGENTS

Tropical infectious diseases are limited by geographic barriers such as oceans, rivers, mountain ranges, or deserts. Rift Valley fever is an excellent example. This mosquito-borne viral agent is indigenous to sub-Saharan Africa and is believed to have as its reservoir *Aedes* mosquitoes that maintain the virus in mosquito eggs between periods of rain. The eggs are deposited in *dambos* (depressions) in East African pastures. After periods of heavy rain, the eggs hatch and the adult mosquito, transovarially infected, can transmit Rift Valley fever virus to sheep and cattle, which in turn amplify the virus transmission. Rift Valley fever was limited to sub-Saharan Africa until 1977 when it suddenly appeared in the Nile delta, where it infected immunologically virgin populations of sheep, cattle, and an estimated 200,000 people. The barrier of the Sahara Desert was breached. Theories abound to explain the spread of Rift Valley fever, but the most likely are the introduction of (i) an infected domestic animal via Lake Nasser, (ii) infected insects blown on the wind, or (iii) an infected person arriving in Egypt by airplane.<sup>17,18</sup>

### LIMITING THE DISTRIBUTION OF TROPICAL INFECTIOUS DISEASES BY PUBLIC HEALTH MEASURES

The distribution of tropical infections can be modified by public health measures. Vaccines, vector control by source reduction and pesticides, treatment, improvement of housing, and drug prophylaxis have been used to limit the distribution of tropical infectious diseases and, at least in the case of smallpox, to eradicate the disease. Several vector-borne diseases, including malaria and yellow fever, were prevalent in the American and Afro-European temperate regions during the 1700s and 1800s. These diseases disappeared outside of the tropics, and some were controlled within the tropics. Sanitation, a raised standard of living, and new technology were primarily responsible. The successes are well-known to most readers. Smallpox was eradicated by 1977 using case finding and vaccination.<sup>19</sup> Major cities were freed of urban yellow fever by control of *A. aegypti* mosquitoes using pesticides and destruction of breeding sites following the methods of General Gorgas.<sup>20</sup> Malaria was eliminated during the 1940s from many temperate zones such as the oases in the Egyptian Western Desert and the islands of Sardinia and Cyprus<sup>21</sup> by mosquito species sanitation. Onchocerciasis in the Americas has been drastically reduced in geographic distribution and incidence by treatment of human carriers with ivermectin.<sup>22</sup> Murine typhus in the

southern United States was dramatically controlled with DDT accompanied by diminution of rat populations.<sup>23</sup>

## DEMOGRAPHICS AND HUMAN BEHAVIOR AFFECT DISTRIBUTION

Human factors influence the distribution of virtually all tropical infectious diseases. Often, this is because people, in the name of progress, disturb the ecology, thus creating breeding sites for vectors and vertebrate hosts. Examples include the following: First, malaria has become epidemic in the western Amazon region of Brazil, where the population has grown 10-fold since 1970. The immigrants are involved in gold mining and forestry and have settled in areas undergoing rapid deforestation.<sup>24</sup> *Anopheles darlingi* mosquitoes breed in standing water of open-cast mining sites and forest clearings. Initially, people from malaria-endemic regions of Brazil arrived already infected to seed the area. Second, the triatomid bugs that transmit Chagas' disease live in the mud walls of homes in Brazil and Argentina.<sup>25</sup> A change in construction methods to eliminate the bug's hiding places, as well as spraying homes with insecticides with residual activity, in some cases has controlled the insect. Third, in 1995 dengue caused more than 4000 illnesses in the Mexican Rio Grande Valley while at the same time only seven indigenous cases of dengue were reported a few kilometers across the river in the U.S. Rio Grande Valley. This difference has been suggested to be a function of better housing and water supplies on the U.S. side of the Rio Grande.<sup>26</sup> Fourth, construction of dams and irrigation projects create ecological changes often favoring transmission of tropical agents. The Diama Dam in the Senegal River basin was implicated in an outbreak of Rift Valley fever in 1987 in Mauritania.<sup>27</sup> Although the disease was not known to be present in the area before 1987, antibody studies of local inhabitants were positive and led to a warning to local government officials and to the governments sponsoring the dam construction of the risk of an epidemic after the dam was completed. This is an example in which the threat was perceived prior to the epidemic, but the warning was not heeded.

## UNKNOWN FACTORS LIMITING DISTRIBUTION: ABSENCE OF YELLOW FEVER FROM ASIA

In some cases, the reason for the distribution of a disease is not intuitively evident. An age-old question is, "Why is there no yellow fever in Asia?" The answer is not known. The yellow fever forest cycle in Africa and South America involves virus, monkey, and mosquito with spillover into humans. Its urban cycle is a three-factor complex involving human beings, *A. aegypti* mosquitoes, and the virus. All of the nonviral factors are present in abundance in Asia, but yellow fever is absent there. Possibly, although unlikely, the virus has never been introduced. Yellow fever is increasingly detected throughout the world in travelers. For instance, in 1996, viremic tourists infected with yellow fever virus near Manaus, Brazil, returned to Switzerland and the United States.<sup>28</sup> One can therefore speculate that the virus must have been introduced by arrival in Asia of viremic persons, in prior times by boat and in recent years by airplane. Possibly, genetically different strains of *A. aegypti* indigenous to Asia are less competent to become infected and transmit yellow fever virus than the mosquitoes

of Africa and South America. This hypothesis has been tested in the laboratory. Although many of the strains from Asia had reduced ability to become infected,<sup>29</sup> the differences were relatively small and did not offer a convincing explanation. Possibly, immunity in humans or primates to dengue or other flaviviruses (serologically related to yellow fever) prevented infection. When challenged with yellow fever virus, monkeys immune to dengue had lower viremia levels than did nonimmune monkeys<sup>30</sup>; however, flavivirus immunity in Africa and South America is substantial and does not prevent yellow fever transmission on those continents. Thus, the factor(s) limiting the geographic distribution of yellow fever remains unknown. If, as some believe, it is a numbers game, and the introduction of yellow fever virus has not yet coincided with the presence of *A. aegypti* in sufficient abundance and during the right season to establish an epidemic, then Asia and the rest of the world must maintain careful surveillance and adequate vaccine supplies so that a catastrophic yellow fever epidemic does not occur.

## GLOBAL CLIMATE CHANGE AND THE SPREAD OF TROPICAL DISEASES

Gradual warming of the earth's surface by 1°F has been recorded during the past 100 years. This warming trend has been predicted to continue by an international panel of experts constituting the Intergovernmental Panel on Climate Change, with 2000 scientists participating.<sup>31</sup> A few scientists still believe that the warming is a natural cycle that will reverse itself. The strongest arguments that the earth will continue to warm come from computer models of the predicted effects of accumulation of greenhouse gases, including carbon dioxide, that capture outgoing heat radiation, warm the atmosphere, and thus warm the earth's oceans and land. The increasing levels of carbon dioxide are amply documented both by direct atmospheric measurements at Mauna Loa in Hawaii and by sampling of CO<sub>2</sub> trapped in ice cores from glaciers in Greenland and the Antarctic region. It is uncertain that CO<sub>2</sub> emissions from automobiles and industries that burn carbon fuels will be controlled in the near future, and thus there is a risk that the current warming trend will accelerate, and that the earth's warmer climates will expand into higher latitudes and altitudes.

The climate models predict increasing temperatures, especially at night and in the higher latitudes. They also point to drastic changes in rainfall patterns, with some parts of the world having flooding and others drought. More severe and more frequent El Niño events, hurricanes, and typhoons are predicted. Warming will bring melting of the major glaciers and polar ice caps with an increase in the sea level. Conservative models predict that at the current rate of CO<sub>2</sub> accumulation, the temperature will rise approximately 3.5°F and the sea level will elevate approximately 6 in. by 2100. The current concentration of CO<sub>2</sub> is approximately 365 ppm, a level not seen on Earth during the past 160,000 years.

Several studies have projected the effects of warming on the spread and intensity of tropical three-factor and four-factor infectious diseases. According to Jetten and Focks,<sup>32</sup> dengue will increase its transmission intensity by 2 to 10 times in much of its current range with a 2°C rise and will spread to areas not now heavily involved, such as the southern United States, Argentina, the Mediterranean, parts of China, and most

of Australia. This prediction takes into account the effects of temperature on adult *A. aegypti* mosquito survival, the parameters of the gonotrophic cycle, the extrinsic incubation period in the mosquito, and the vector size, which affects the frequency of feeding (see Climate and Disease Distribution). According to this model, not only will dengue spread but also the transmission season will be prolonged in much of the mosquito's range, and the risk of secondary infection in younger people, and thus of severe dengue disease, will increase.

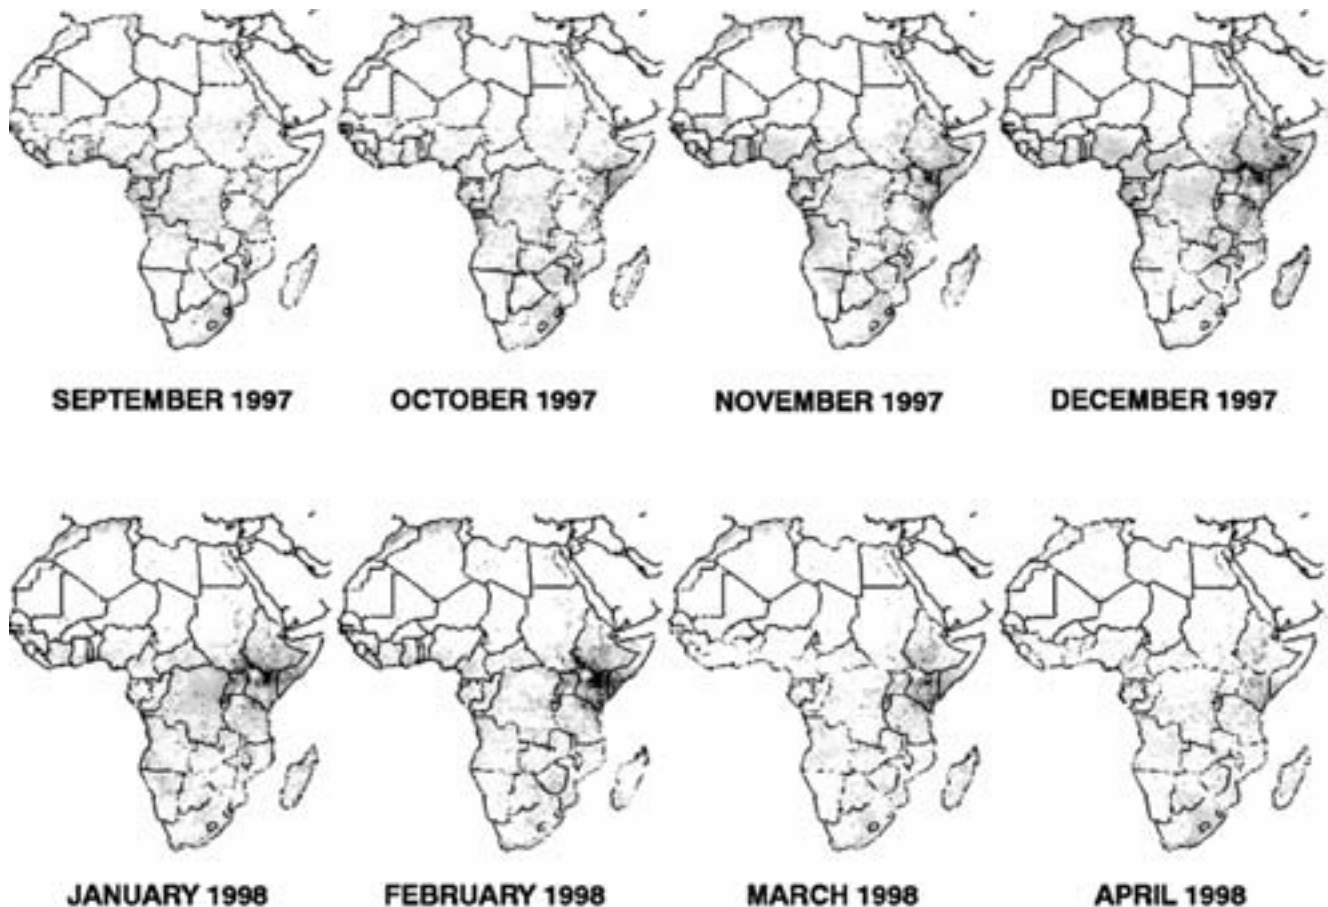

Schistosomiasis is a disease caused by trematodes that are obliged to pass part of their life cycle in water and snail hosts. If the climate changes, what are now temperate areas in Europe, Asia, and the Americas are predicted to reach temperatures that will support transmission of human schistosomes in host snails, now limited to the tropics.<sup>33</sup>

According to Killick-Kendrick,<sup>34</sup> leishmaniasis could flourish in southern England by 2025 if the prediction of a 24°C (75°F) summer is correct. He notes that *Phlebotomus perniciosus* has already been found in England; it is an excellent vector of *Leishmania infantum* in southern Europe, could survive the predicted climate, and could maintain the life cycle of *L. infantum* at 24°C. Reservoir hosts such as dogs and immunosuppressed persons are available to support the parasite, and thus the public should be concerned.

Predictions of increased distribution of tropical infectious diseases have also been made for cholera,<sup>35,36</sup> St. Louis and Western equine encephalitis,<sup>37</sup> vampire bat rabies,<sup>38</sup> and malaria.<sup>39,40</sup> The acceptance of these predictions should be qualified, keeping in mind the doubts some scientists harbor about the inevitability of climate change. In addition, the geographic distribution and incidence of diseases are not solely governed by climate. Arguably more important are public health measures, including treatment, drug prophylaxis, immunization, education, and vector control. If the predicted warming is accompanied by technical advances in disease control and an improvement in the standard of living, including housing with screens and air-conditioning, these measures may well dampen the transmission and spread of insect-borne diseases.

## THE FUTURE OF GEOGRAPHIC STUDIES

In the past decade, geographic information systems (GIS) have given new tools to the disease ecologist for studying landscape and vegetation. Remote sensing with satellite imagery (Fig. 2-2) has been used to chart surface changes in vegetation and to predict weather patterns such as El Niño or southern oscillation through measurements of ocean surface temperature on a global basis. Predictions of cholera<sup>36</sup> and

**FIGURE 2-2** Monthly Advanced Very High Resolution Radiometer (AVHRR) images of the Normalized Difference Vegetation Index (NDVI) of continental Africa during the 1997–1998 ENSO warm event. Data depicted are the degree of deviation from the long-term mean calculated for the period January 1982 to May 1998 in NDVI units. Darkly shaded areas have received higher than average rainfall and can be used to determine conditions associated with outbreaks of Rift Valley fever. (From Linthicum KJ, Anyamba A, Tucker CJ, et al: Climate and satellite indicators to forecast Rift Valley fever epidemics in Kenya. *Science* 285:397–400,1999.)

Rift Valley fever<sup>41</sup> outbreaks now appear to be feasible. In the case of Rift Valley fever, analysis of the outbreaks of the disease from 1950 to 1998 indicates the potential to predict the disease as much as 5 months in advance.<sup>42</sup> Can this technology also lead to a better understanding of the distribution and incidence of other three- and four-factor diseases, such as malaria, dengue, and hantavirus pulmonary syndrome?

## Epidemiology and Biostatistics

EDWARD T. RYAN  
MEGAN MURRAY

Epidemiology is the science of investigating the occurrence, causes, and prevention of disease in human populations. Epidemiologic tools may be used to estimate disease frequency, uncover or confirm associations between risk factors and disease occurrence, and define the impact of preventive and curative measures to combat disease. As one of the primary disciplines of the field of public health, epidemiology is of great importance to human health worldwide, especially in the developing world. A fundamental understanding of epidemiologic principles—including basic terminology; study design and hypothesis testing; and data collection, analysis, and interpretation—is, therefore, necessary to the understanding of biomedical sciences.

### OVERVIEW AND TERMINOLOGY

#### Measures of Disease Frequency

*Prevalence* is a measure of the total number of existing cases of a disease or condition in a specific population at a particular time. Prevalence is usually expressed as a fraction or percentage of a population, but it can also be given as the number of cases per 1000, 10,000, or 100,000 people. In contrast to prevalence, which enumerates *all* cases of a disease, *incidence* is a measure of the number of *new* cases of disease occurring over a specified period. Incidence is, therefore, expressed as the number of cases that occurred in a population of a given size per a unit time. Thus, if a cohort of 1000 individuals is followed for 1 year and 100 of these individuals develop a specific disease, the incidence rate of that disease would be 0.1, or 100 per 1000 per year.

#### Measures of Effect

In addition to measuring frequency of occurrence of a disease, epidemiologic studies measure the strength of an association between a specific risk factor and the incidence of a disease or medical condition, or between a specific intervention or treatment and the prevention or resolution of a disease. For instance, the effect of a risk factor on disease frequency can be estimated by comparing the incidence of disease in a group that has been exposed to a specific risk factor to the incidence of disease in a group that has not been exposed.

### Infectious Disease Terms

There are a number of definitions specific to the epidemiologic study of infectious diseases. A disease that occurs regularly in a population is said to be *endemic*. When a disease occurs at a frequency higher than is expected, it is said to be *epidemic*. A localized epidemic may be referred to as an *outbreak*. Diseases in animals are said to be *enzootic* or *epizootic*. After infection, there often follows a period of *latency*, defined as the duration of time from infection to onset of infectiousness. The period of time immediately following infection may also be an *incubation* period, defined as the time from infection to development of symptomatic disease. If the incubation period is longer than the latent period for a specific disease, individuals may infect others prior to the onset of recognizable illness. An *attack rate* refers to the proportion of a population that develops an infectious disease over a given period. The term *secondary attack rate* refers to the proportion of *exposed* individuals who become ill. The secondary attack rate is often measured among the household members of a known index case, since it is relatively easy to count the number of exposed individuals and follow them over time.

The *basic reproductive number*, often expressed as  $R_0$ , is defined as the expected number of secondary infectious cases generated by an average infectious case in a population in which everyone is susceptible. This quantity determines the potential for an infectious agent to start an outbreak, the extent of transmission in the absence of control measures, and the ability of control measures to reduce spread.  $R_0$  can be expressed as a product of the number of contacts each infectious individual has per unit time ( $k$ ), the probability of transmission per contact between an infectious case and a susceptible person ( $b$ ), and the mean duration of infectiousness,  $D$ :

$$R_0 = bkD$$

Although it is a highly simplified summary of a pathogen's epidemic potential,  $R_0$  may be used to predict outcome following an introduction of an infection into a population. If  $R_0$  is greater than 1, the number of people infected will grow and an epidemic will take place; if  $R_0$  is less than 1, the disease will die out.

In real epidemics, it is useful to replace the *basic reproductive number* with the *effective reproductive number*, denoted  $R$ , which is defined as the *actual* average number of secondary cases infected by a primary case.  $R$  is usually less than  $R_0$ , since it reflects both the impact of control measures instituted over time and the depletion of a susceptible population as previously infected individuals acquire immunity. *Herd immunity* results when a vaccine not only protects a vaccinated individual from contracting an infection but also prevents that individual from spreading the infection to others.

### STUDY DESIGN

Understanding scientific–medical studies requires knowledge of a number of fundamental epidemiologic and statistical concepts, the first of which concerns study design. Studies may be designed to measure disease frequency (incidence and prevalence) or to measure an effect (e.g., how effective is drug A compared with drug B in the treatment of individuals with a certain medical condition). A classic type of study that

measures disease frequency is a *surveillance study*, which tracks the frequency of a disease in a population over time. It is effectively a reporting system. It may be *active*, in which case people with disease are actively sought, or *passive* where cases are reported that present to medical attention. It may be hospital- or clinic-based or community-based. It may report specific well-defined diseases or, if diagnostic capabilities are limited, it may report syndromes (e.g., the syndrome of ulcerative genital disease as opposed to genital herpes, chancroid, or syphilis, specifically). Surveillance systems are a fundamental tool in public health because they provide critical information on disease burden and changes in disease frequency over time that may alert public health authorities to epidemic disease.

Studies that *measure an effect* may measure the effectiveness of a new drug or vaccine; alternatively, they measure the effect of a possible risk factor on disease frequency (e.g., the effect that smoking has on the risk of developing lung cancer). The optimal study for measuring effect is a *clinical trial*. Randomized clinical trials are prospective studies in which individuals are randomized to one of at least two study arms and followed for the outcome of interest over time. The major advantage of this type of study is that the random nature of group assignment ensures that people in one group will not differ systematically from people in another group in some way that would influence outcome. Another way to say this is that the purpose of randomization is to eliminate potential confounding factors (whether suspected or not suspected) that are associated with both exposure and outcome.

If the random assignment is completely unknown to both the study participants and researchers, it is called a *double-blind randomized trial*. If one of the study arms receives a treatment or intervention and the other receives a placebo, the trial is called a *placebo-controlled trial*. Since it is unethical to offer one group a placebo if there is available a treatment of known benefit, many trials compare the efficacy of a new intervention to that of a standard therapy; these trials are called *equivalence studies*. An example of a randomized double-blind equivalence study would be one that compares the efficacy of two drugs, drug A and drug B, for the treatment of shigellosis. To ensure that both participants and researchers are blinded to the intervention, the drug preparations should look and taste the same, be administered on the same dosing schedule, and given by the same route. Follow-up of the two groups should be identical.

It is often impossible to conduct a clinical trial, especially when the exposure of interest is not an intervention or a treatment but some kind of environmental or genetic factor. In this case, a *cohort study* can be conducted to estimate association between risk factor and outcome. In a cohort study, groups of individuals with different exposure histories are identified and followed over time. As an example, imagine that we want to study the relationship between smoking and lung cancer. We could identify individuals who smoke and those who do not and follow them over time to see if the incidence of lung cancer between the two cohorts is different. This type of study has several possible shortcomings, one of which is that it may take years or decades for an individual to develop a disease or outcome after initial exposure. Another problem inherent in this type of study is the fact that the two cohorts of exposed and unexposed people may differ in ways other than just the basis of the exposure of interest (a *confounding influence*). For example,

a confounding influence in our study may be the effect of alcohol consumption on the development of lung cancer (for instance, if individuals who drink heavily were more likely to smoke than those who do not drink heavily).

An alternative study design is a *case-control study*. In this type of study, exposures of people who experience an outcome of interest are compared to exposures of those who have not had such an outcome. This type of study is especially useful for a rare disease or when there is a prolonged period of time between exposure and outcome. Continuing our example of examining the relationship of smoking and lung cancer, in a case-control study, we would identify individuals who have developed lung cancer and a group of “controls” who have not developed lung cancer. We could then ascertain the smoking histories of individuals in the study and try to determine whether they were consistently different between cases and controls. Since case-control studies often involve retrospective collection of exposure data obtained after a subject knows his or her diagnosis, there is a potential for *recall bias*. Another potential problem in case-control studies involves the selection of controls. Ideally, cases should be chosen from the population that gave rise to cases and should be selected without regard to exposure status. Case-control and cohort studies are also referred to as *observational studies*, since there is no intervention.

## HYPOTHESIS TESTING

When designing a study, researchers should first *state the hypothesis* that they want to test. For example, “we hypothesize that drug A is effective in treating salmonellosis.” The hypothesis should be stated before data are collected. A common pitfall of studies is to first collect data and *then* to analyze data for comparisons that reach statistical significance. Such a fishing expedition may uncover real differences, but may also uncover differences related to chance alone.<sup>1</sup>

A placebo-controlled double-blind randomized trial would be the best way to test our hypothesis that our new drug A is “effective” in treating individuals with salmonella gastroenteritis. When designing this study, researchers should first select relevant and measurable endpoints that will distinguish whether individuals who get the drug “do better.” Primary endpoints may be days of diarrhea; days of fever; duration of bacterial shedding of salmonella organisms in stool; and/or the presence or absence of infectious complications, bacteremia, or death. These outcomes should be as clinically relevant and precise as possible; that is, definitions of what constitutes diarrhea and fever should be established before the study is undertaken, the same amount of stool and blood should be collected and processed from all study enrollees to ensure equality of assessment, and data should be recorded and reported as accurately and completely as possible.

After the hypothesis is stated, the researchers should next formulate the *null hypothesis*. In this step, the investigators should assume that no true difference exists between the two study groups (those who get drug A and those who get the placebo). A decision should then be made as to what constitutes a statistically significant result. *Statistical significance* is usually conveyed through a statistic known as the *P value*; results are often considered significant if the *P value* is less than a cut-off value (or “alpha level”) of 5%. The *P value* refers

to the probability that one would observe a result equal to or more extreme than the study result under the null hypothesis. One way to interpret this is to say that if a difference is shown between the two groups, there is a 95% chance that the difference is true (or a less than 5% chance that the difference is due to chance alone).

The *alpha level* is a cut-off value for a *P* value for a hypothesis test that is often set, somewhat arbitrarily, at 0.05. A *type I error* occurs when the null hypothesis is incorrectly rejected when it is in fact true, that is, when there is no difference between drug A and a placebo. A test with an alpha level of 0.05 should lead to type I errors no more than 5% of the time. Unlike the *P* value that varies with the data, alpha levels are chosen in advance and indicate the specific *P* value that will be considered significant. A *type II (or beta) error* occurs when the null hypothesis is not rejected even when there is truly a difference between the two arms of the study, that is, between drug A and the placebo. Type II errors may occur when a study is not large enough to detect a difference, or when individuals are not followed for an adequate amount of time for differences between groups to become apparent. Most well-designed studies aim for a type II error rate between 10% and 20%. The *power* of a study refers to the probability that the null hypothesis is rejected when it is false, and it is thus given the expression

$$\text{Power} = 1 - \text{Probability of a type II error.}$$

Therefore, most studies aim for 80% to 90% power (i.e., an 80% to 90% chance that if the null hypothesis is not rejected it is correct). It is this power calculation that determines the number of individuals who need to be enrolled in a study.

Only after the hypothesis has been stated and a study appropriately designed and adequately powered should data be collected and stored. Once this is completed, data analysis may begin. In this step, investigators determine the estimated effect of the intervention or exposure, and the probability that the observed difference between the two study groups would occur if no true difference exists in the larger population.

## DATA EXPRESSION AND ANALYSIS

Data may be expressed in many ways. When an exposure or outcome is expressed in terms of a continuous variable such as age or weight, the differences between groups may be expressed by comparing *mean* or *median* values for the two groups. Both these statistics are measures of central tendency, meaning that they describe the middle, or average, value of the data. The mean is the *arithmetic* average, which is simply obtained by summing the observations and dividing the sum by the number of observations. For instance, if we measure the days of diarrhea following administration of drug A to patients with salmonellosis, we may find that one patient had diarrhea for 2 days, another for 3 days, another for 4 days, another for 5 days, and another for 20 days. The mean would be a summation divided by the number evaluated ( $2 + 3 + 4 + 5 + 20$  [equals 34] divided by 5 = 6.8). The *median* is the value that divides the data in half; 50% of the observations have values lower than the median, and 50% have values greater than the median. The median is also referred to as the 50th centile. Using the median rather than the mean lessens the impact of outliers, since the actual values of extreme data

points do not affect the median. Another way of reducing the effect of extreme outlier observations is to use the *geometric mean*, which is often used with data measured on a logarithmic scale. The geometric mean is calculated by multiplying the observed values and taking the *n*th root, where *n* is the number of observations. For the preceding example, this would be given by

$$\sqrt[5]{(2)(3)(4)(5)(20)} = 4.7.$$

The term *standard deviation* measures the spread of the individual observations around the mean. It is given by the formula

$$s = \sqrt{\frac{\sum (X - \bar{X})^2}{n - 1}}.$$

where *X* represents the value of each individual observation,  $\bar{X}$  represents the mean, and *n* represents the number of observations. The *standard error of the mean* indicates the degree of uncertainty in calculating estimate from a sample. A standard error may be calculated from the standard deviation by dividing the standard deviation by a square root of *n* (with *n* representing the number of values measured).

*Range* refers to the interval from the minimum to the maximum value in a set of quantitative measurements. For instance, the arithmetic mean in our example would be 6.8, the geometric mean would be 4.7, the median would be 4, and the range would be 2 through 20.

Data that are *normal* or *normally distributed* are symmetrically distributed around a mean. A classic example of normally distributed data is a bell-shaped curve (e.g., a population-based IQ evaluation; Fig. 3-1).

Characteristics that we might want to study may be measured in a variety of ways. Observed data may be *dichotomous*, *categorical*, or *continuous*. If data can take only one of two values, they are defined as *dichotomous*. Returning to our smoking and lung cancer example, we could describe smoking in terms of the dichotomous variables “ever” or “never” smoked. *Categorical* observations have values that fit into categories. For example, we might characterize race or ethnicity using a categorical variable. Some data categories describe ascending levels of intensity or severity. For example, we could describe smoking history as “none,” “light,” “moderate,” and “heavy.” When categorical data are ordered in this way, they are *ordinal*. Finally, data may be measured on a *continuous* scale. Again, referring to our smoking

FIGURE 3-1 Normal distribution.

example, we could measure smoking in terms of the number of cigarettes consumed. At analysis, continuous data may be transformed into categorical data (but not vice versa).

Once we have summarized our data into the groups we are comparing, we need to decide whether the data differ between groups. If data are dichotomous, we may compare proportions, for example, the proportion of “ever” smokers who develop lung cancer to “never” smokers who develop lung cancer. For instance, imagine in our study that 5 smokers develop lung cancer out of a cohort of 100, while only 1 of 100 nonsmokers develops lung cancer. These data could be presented in a table of observed frequencies as follows:

	Lung Cancer	No Lung Cancer	Total
Ever smoked	5	95	100
Never smoked	1	99	100
	6	194	200

Under the null hypothesis, we assume that there is no difference in the incidence of lung cancer among smokers and nonsmokers. Given that 6 cases of lung cancer occurred among the 200 people we followed, we can come up with a table of “expected” frequencies under the null hypothesis.

	Lung Cancer	No Lung Cancer	Total
Ever smoked	3	97	100
Never smoked	3	97	100
	6	194	200

We can use the *chi-square test* statistic to ask how likely it would be that we obtained the observed frequencies if the null hypothesis were true. The chi-square statistic is given by the formula

$$X^2 = \sum_{\text{all cells}} \frac{(O - E)^2}{E}$$

where  $O$  is observed frequency and  $E$  is expected frequency. If the chi-square test is small, this suggests that there is no difference between the groups; if it is large, we assume that a difference exists.

Other statistical tests are available to analyze data. The choice of optimal test depends on a number of variables, including data type and number of groups. For instance, for continuous data that are normally distributed, we could compare the means of two groups using the *t test* for comparing means. When data are not normally distributed, other tests would be required; these usually are based on “order statistics” and include such nonparametric methods as the *Mann-Whitney U Test*, the *Kruskal-Wallis* and the *Wilcoxon matched rank test*, among others. The *ANOVA* (analysis of variance) test may be used to compare more than two groups that are normally distributed. The Mann-Whitney U test is used for evaluating two groups that are not normally distributed, and the Kruskal-Wallis test may be used for evaluating more than two groups that are not normally distributed.

Analysis of data may disclose “associations.” For instance, returning to our example of smoking and lung cancer, we may find that smoking and lung cancer are statistically associated. Although variables that are found to be associated with an outcome are often called *risk factors*, a statistical association does not imply a cause and effect relationship between that variable and outcome. The *relative risk* is the probability of an outcome if a risk factor/association is present divided by the probability of the outcome if the risk factor/association is absent. For instance, in our example of the cohort study of smokers and nonsmokers, we imagined a study in which we have followed 100 individuals who smoke and 100 individuals who never smoked. We saw that 5 of the 100 smokers developed cancer (probability 0.05), but that only 1 of 100 nonsmokers developed lung cancer (probability 0.01). The relative risk is, therefore, 0.05 divided by 0.01, or 5. A relative risk of 5 implies that individuals who smoke are five times more likely to develop lung cancer than individuals who do not smoke.

In case-control studies, it is the researcher who determines how many study and control participants are evaluated, and so a true disease frequency in the population as a whole cannot be established. In this case, we cannot estimate the relative risk, since we do not actually know the risk of disease in the unexposed population. An approximation of the relative risk for case control studies is the *odds ratio*. To understand the difference between a risk and an odds ratio, think of the probability (or risk) of throwing a six-sided die in a game of chance and having the die land with six black dots facing up (1 in 6 chance). The odds of throwing a six on the other hand will be the number of times the die will land with six black dots showing divided by the number of times six dots will not be uppermost (1 to 5). An odds ratio is, therefore, the odds of developing an outcome if an association is present, divided by the odds of an outcome if the association is absent. Both the relative risk and the odds ratio are easy to calculate from a  $2 \times 2$  table.

	Lung Cancer	No Lung Cancer	Total
Ever smoked	A	B	A + B
Never smoked	C	D	C + D
	A + C	B + D	A + B + C + D

$$RR = \frac{A/(A+B)}{C/(C+D)}$$

$$\begin{aligned} OR &= \frac{[A/(A+C)]/[C/(A+C)]}{[B/(B+D)]/[D/(B+D)]} \\ &= \frac{A/C}{B/D} = \frac{AD}{BC} \end{aligned}$$

*Confidence intervals* are a way of combining information about the strength of an association with information about the effects of chance in obtaining the observed results. A 95% confidence interval (CI) is most commonly used. An association is usually reported as an odds ratio (OR) or relative risk (RR) with a 95% CI.

The final stage of analyzing a study is extrapolation. We may extrapolate to an individual or to a group. For instance,

based on a relative risk or odds ratio of 5 for smoking and lung cancer, we could conclude that if an individual smoked, he or she may be five times more likely to develop lung cancer than if he or she did not smoke. We may also speak of an *attributable risk percent*. The advantage of this concept is that it allows us to think of a portion of the risk of developing a disease that may be eliminated among those who do not have the risk factor. Attributable risk percentage may be thought of as

$$(RR - 1/RR) \times 100\%$$

where RR is relative risk.

For instance, in our study, we found that smoking was associated with a relative risk of 5 of developing lung cancer. This may not seem like an overly large risk of developing lung cancer; however, the attributable risk percent is  $5 - 1/5 = 80\%$ . This suggests that 80% of lung cancer in our study population could have been prevented if our study participants had never smoked.

### UNDERSTANDING DIAGNOSTIC LABORATORY TESTS

In many instances, laboratory tests are part of a case definition (e.g., detection of serum antibodies against human immunodeficiency virus [HIV] in a study involving individuals infected with HIV). It should be recalled that a test is often a surrogate marker to distinguish a disease-free group from a diseased group. Assuming a normal distribution in both groups of whatever marker we are measuring (e.g., a serum antibody level), we can imagine that the disease-free and diseased groups do not overlap at all with regard to the specific blood test of interest (Fig. 3-2A). Often, however, the two groups do overlap, and some individuals in the diseased group will have tests with lower values than some of the individuals in the disease-free group (Fig. 3-2B).

In establishing the utility of a test, therefore, we must first establish the reference interval for disease-free individuals. *Sensitivity* and *specificity* of a test are then measured compared with a “gold standard.” *Sensitivity* measures the probability that those with a disease will have a positive test when individuals with the disease are identified by the gold standard. *Specificity* measures the probability that those who do not have the disease will test negative by the test being evaluated. There usually is a trade-off between the sensitivity and specificity of a specific test. For example, if we choose X as the cut-off value for a positive test on Figure 3-2B of overlapping curves, we will achieve 100% sensitivity—but at the cost of misclassifying many negative cases as positive ones, that is, reducing specificity. Conversely, we could maximize specificity by moving our cutoff value for a positive test rightward to the Y position, but in so doing, we would compromise our ability to identify a true case of disease.

For example, imagine that we are evaluating a new test to diagnose schistosomiasis, and imagine that we will compare this test to a gold standard in a village with a population of 1000 individuals of whom 500 actually have schistosomiasis by our gold standard. Imagine that our new test correctly identifies 400 infected individuals but incorrectly identifies 100 truly infected individuals as not having schistosomiasis when in fact they are infected (*false negative*). Also imagine that our new test incorrectly labels 50 individuals as having schistosomiasis who do not (*false positive*).

Test	Gold Standard Disease	Gold Standard Disease-Free
Positive	400 (a)	50 (b)
Negative	100 (c)	450 (d)
	500	500

Sensitivity and specificity are calculated as

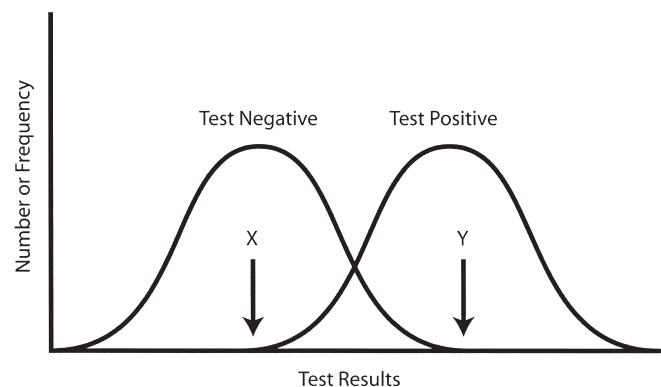

$$\text{Sensitivity} = \frac{a}{a + c} = \frac{400}{500} = 0.80 \text{ or } 80\%$$

$$\text{Specificity} = \frac{d}{b + d} = \frac{450}{500} = 0.90 \text{ or } 90\%$$

Our test will, therefore, have a sensitivity of 80% and a specificity of 90%. The actual utility of this test, however, will rest not only on its sensitivity and specificity but also on the prevalence of the disease in question in our population of interest. In our preceding example, there was a 50% prevalence of schistosomiasis (500 infected individuals who lived in a population of 1000). If we assume that the “true” prevalence of schistosomiasis in a different village is 20%, at a population level, the average individual in that village will have a 20% chance of having the disease before the test is performed (in reality, certain individuals will be at higher or lower risk of having schistosomiasis on the basis of age, gender, and other factors).

A

B

**FIGURE 3-2** A, Normal distribution in which two groups do not overlap. B, Two groups that overlap.

Assuming that we are evaluating 1000 individuals (with 20% of them having the disease), and assuming that we are using our new test with a sensitivity of 80%, we would assume that 160 of the 200 individuals with the disease will be correctly identified by the test:

<b>20% Probability Village X</b>		
<b>Test</b>	<b>Gold Standard Disease</b>	<b>Gold Standard Disease-Free</b>
Positive	160	80 false positives
Negative	40 false negatives 200	720 800

The remaining 20% of these individuals will be incorrectly labeled as negative ( $n = 40$ ; false negatives). Specificity equals 90%; therefore, 90% of those who are disease-free will be correctly labeled as negative (90% of 800; 720 true negatives). The remaining 10% of individuals who are disease-free will be incorrectly labeled as positive (10% of 800; 80 false positives).

Now let us imagine that we are applying our same test in a different village in which schistosomiasis is much more prevalent and 75% of the population has the disease:

<b>75% Probability Village Y</b>		
<b>Test</b>	<b>Gold Standard Disease</b>	<b>Gold Standard Disease-Free</b>
Positive	600	25 false positives
Negative	150 false negatives 750	225 250

Finally, let us imagine that we use our test in a third village, in which schistosomiasis is much rarer and the true probability of disease is only 2% (only 2% of the population is infected). Then our table would look like this:

<b>2% Probability Village Z</b>		
<b>Test</b>	<b>Gold Standard Disease</b>	<b>Gold Standard Disease-Free</b>
Positive	16	98 false positives
Negative	4 false negatives 20	882 980

Now, let us analyze the predictive value of positive and negative test results in each of these villages. The *positive predictive value* refers to the probability that one who tests positive truly has the disease, while the *negative predictive value* refers to the probability that one who tests negative actually does not have the disease. The crucial point to understand is that the predictive value depends not only on the sensitivity and specificity of the test itself but also on the disease prevalence in the population being evaluated.

<b>Test</b>	<b>Gold Standard Disease</b>	<b>Gold Standard Disease-Free</b>	
Positive	a = Number of individuals diseased and positive	b = Number of individuals disease-free and positive	a + b = total number of test positives
Negative	c = Number of individuals diseased and negative	d = Number of individuals disease-free and negative	c + d = total number of test negatives

The following formulae are used for calculating the predictive value of a positive test and the predictive value of a negative test:

$$\text{Predictive value of a positive test} = \frac{a}{a+b} \quad \text{Proportion of individuals with a positive test who actually have the disease}$$

$$\text{Predictive value of a negative test} = \frac{d}{c+d} \quad \text{Proportion of individuals with a negative test who actually do not have the disease}$$

Using the preceding calculated numbers, and assuming a 2% pretest probability of disease (as in Village Z):

$$\text{Predictive value of a positive test} = \frac{a}{a+b} = \frac{16}{16+98} = 14\%$$

$$\text{Predictive value of a negative test} = \frac{d}{c+d} = \frac{882}{4+882} = 99.5\%$$

Similarly, if we assume a 75% pretest probability as in Village Y,

$$\text{Predictive value of a positive test} = \frac{a}{a+b} = \frac{600}{600+25} = 96\%$$

$$\text{Predictive value of a negative test} = \frac{d}{c+d} = \frac{225}{150+225} = 60\%$$

Therefore, using exactly the same test, with exactly the same sensitivity and specificity, we can generate the following table of positive and negative predictive value of our test in villages with different prevalences of the disease in question:

	<b>Pretest Probability</b>		
	<b>2% (Village Z)</b>	<b>20% (Village X)</b>	<b>75% (Village Y)</b>
Predictive value of a positive test	14%	66.7%	96%
Predictive value of a negative test	99.5%	94.7%	60%

This means that there is an 86% chance that a positive test obtained in a Village Z with a 2% pretest probability of

disease is falsely positive. Similarly, there is a 40% chance that a negative result is in fact falsely negative in Village Y with a pretest probability of disease of 75%. This is despite the fact that we are using the same test with the same sensitivity and specificity in each village. It is, therefore, crucial to understand that the interpretation of laboratory tests (whether in a study or in clinical practice) should be understood in context.

## Social and Cultural Factors in Tropical Medicine: Reframing Our Understanding of Disease

DAVID A. WALTON  
PAUL E. FARMER  
REBECCA DILLINGHAM

### BARRIERS TO CARE AND THE PERSISTENT PATHOGENS: A BIOSOCIAL APPROACH

By the close of the 20th century, the world's ranking infectious pathogens—from well-known malaria and filariasis to the more recently described human immunodeficiency virus (HIV)—could be controlled by the tools of modern medicine and public health. And yet, none of these diseases, or other important “tropical diseases,” has been brought to heel. None of them, even those without a nonhuman host, have been eradicated. Some epidemic diseases continue to expand. Still others mutate to become drug-resistant pathogens for which there are no clear therapies. Vaccines, in the event they exist, are not always delivered effectively in the settings in which they are most needed. The cumulative burden of these diseases remains unchanged, and in some cases is growing; this burden weighs most heavily on the world's poorest billion inhabitants.

This chapter examines this central irony of 21st century medicine: the persistence of morbidity and mortality due to infectious diseases years after effective vaccines, cures, suppressive treatments, and preventive strategies have been discovered. The forces inhibiting the successful application of existing scientific knowledge are not primarily biological or cultural; they are, rather, economic and structural barriers to change. Using what may be called a *biosocial model*, this chapter will describe these barriers to health.

Because modern epidemics are almost invariably rooted in social conditions, some long-standing and others changing rapidly, inquiry that does not draw on the social sciences is unlikely to offer a comprehensive or accurate understanding of these plagues. The mechanisms by which social forces shape epidemics are not readily revealed by single methodologies but rather by interdisciplinary research that links

qualitative and quantitative methods. A biosocial model calls into question the very term *tropical diseases*, since many of the pathogens discussed in this textbook caused, in the past, significant mortality far from the tropics. The dozen or so diseases grouped under this rubric have little in common in terms of pathogenesis, chronicity of infection, modes of transmission (some are vector-borne, others are not), or efficacy of existing control and treatment strategies. But whether we consider what are often termed the “neglected diseases” (African trypanosomiasis, dengue, leishmaniasis, schistosomiasis, Chagas disease, lymphatic filariasis, and onchocerciasis) or the largest infectious killers (diarrheal and respiratory diseases, HIV, tuberculosis [TB], and malaria), there are important similarities to consider. All of these diseases afflict the poor disproportionately and are linked to social conditions. For each disease, there exist important deliverables: new and improved diagnostics and therapeutics that could affect the distribution and outcomes of these epidemics. In each instance, new discoveries could substantially decrease the morbidity and mortality associated with these persistent pathogens, but social and economic barriers have to date hampered effective control strategies.

The mechanisms by which social forces delay health progress are in large measure those leading to the propagation of new epidemics such as acquired immunodeficiency syndrome (AIDS). We begin this review with a case study of AIDS and TB in rural Haiti, since many of the barriers to care are best seen by closely examining individual illness trajectories and since TB is often the leading cause of death among patients living with HIV disease in resource-poor settings. The case study is followed by a review of structural barriers to effective AIDS prevention and care. Next, a brief description of the economic impact of malaria and the challenges of implementing insecticide-treated bednets (ITNs) illustrates how poverty, the primary social barrier, limits effective implementation of proven prevention strategies. Finally, we will explore the implications of this review for effective control of other leading infectious killers.

### AIDS AND TUBERCULOSIS IN HAITI: JOSEPH'S STORY

On the afternoon of March 17, 2003, four men appeared at the public clinic in Lascahobas, Haiti, each carrying a leg of a makeshift stretcher. (The Lascahobas clinic in Central Haiti is a recent partnership between the nonprofit organization Partners in Health/Zanmi Lasante and the Haitian Ministry of Health. It is rural Haiti's second full-service AIDS clinic and also provides a range of other health services.) On the stretcher lay a young man, eyes closed, seemingly unaware of the 5-mile journey he had just taken on the shoulders of his neighbors. When they reached the clinic after the 4-hour trip, they placed the young man, named Joseph, on an exam table. The physician tried to interview him, but Joseph was already stuporous. His brother recounted the dying man's story.

Joseph, 26, had been sick for months. His illness had started with intermittent fevers, followed by coughing, weight loss, weakness, and diarrhea. His family, too poor, they thought, to take him to a hospital, brought Joseph to a traditional healer. Joseph would later explain: “My father sold nearly all that he had—our crops, our land, and our livestock—to pay the healer,

but I kept getting worse. My family barely had enough to eat, but they sold everything to try to save me.”

Joseph was bed-bound 2 months later. He became increasingly emaciated and soon lost all interest in food. As he later recalled, “My mother, who was caring for me, was taking care of skin and bones.”

Faced with what they saw as Joseph’s imminent death, his family purchased a coffin. Several days later, a community health worker, employed by the Lascahobas clinic, visited their house. The health worker was trained to recognize the signs and symptoms of TB and HIV and immediately suspected that the barely responsive Joseph might have one or both of these diseases. Hearing that their son might have one last chance for survival, Joseph’s parents pleaded with their neighbors to help carry Joseph to the clinic, since he was too sick to travel on a donkey and too poor to afford a ride in a vehicle.

At the clinic, Joseph was diagnosed, as per the community health worker’s suspicions, with advanced AIDS and disseminated TB. He was hospitalized and given antiretrovirals and antituberculous medications (Fig. 4-1A). Like his family, however, Joseph, too, had lost faith in the possibility of recovery. He remembers telling his physician, early in the course of his treatment, “I’m dead already, and these medications can’t save me.”

Despite his doubts, Joseph dutifully took his medications each day, and he slowly began to improve. Several weeks later, he was able to walk. His fevers subsided and his appetite returned. After discharge, he received directly observed therapy (DOT) for both AIDS and TB from a neighbor serving as an *accompagnateur*.<sup>1</sup> After 4 months of therapy, Joseph had gained 30 pounds (Fig. 4-1B).

Now, over a year later, Joseph is employed as an HIV outreach worker, often speaking in front of large audiences about his experience (Fig. 4-1C). “When I was sick ... I couldn’t farm the land, I couldn’t get up to use the latrine; I couldn’t even walk. Now I can do any sort of work. I can walk to the clinic just like anyone else. I care as much about my medications as I do about myself. There may be other illnesses that can break you, but AIDS isn’t one of them. If you take these pills, this disease doesn’t have to break you.”

## STRUCTURAL BARRIERS TO EFFECTIVE AIDS AND TUBERCULOSIS CONTROL

Joseph’s experience is typical in many ways and instructive in most. He is one of tens of millions worldwide suffering from HIV disease and TB; he lives in great poverty; he sought care unsuccessfully until he simply gave up. His family did what they could to save his life, selling off meager assets and receiving contradictory advice from neighbors and from traditional healers in a country in which trained medical personnel are rare\* and most care is fee-for-service. Joseph’s

experience is exceptional in that he lived in an area of Haiti in which treatment for both AIDS and TB has recently come to be considered a public good and made available to poor patients who cannot pay user fees.<sup>2</sup> Treatment for these two chronic infectious diseases is supervised not by physicians or nurses, who do play a role in the diagnosis of illness, but by community health workers who are also one’s neighbors.<sup>3</sup> In the following sections, we review these topics in greater detail by examining an emerging literature that explores socioeconomic barriers to effective care for AIDS and tuberculosis.

## The “Brain Drain”

One significant and often-invoked barrier to effective care in resource-poor settings is the lack of medical personnel. In what has been termed the “brain drain,” large numbers of physicians and nurses are leaving their home countries in order to pursue opportunities abroad, leaving behind health systems that are understaffed and ill-equipped to deal with the epidemic diseases that ravage local populations.<sup>†</sup> The World Health Organization (WHO) recommends a minimum of 20 physicians and 100 nurses per 100,000 persons, but recent reports from that body and others have confirmed that many countries, especially in sub-Saharan Africa, fall far short of those targets. Over half of these countries register fewer than 10 physicians per 100,000 population. In contrast, the United States and Cuba boast, respectively, 279 and 596 doctors per 100,000 population. Similarly, the majority of sub-Saharan African countries fail to meet even half of the WHO minimum standard for adequate nursing coverage.<sup>‡</sup>

These national aggregates, while appalling, do not reveal the further inequalities in health-care staffing within countries. Rural-urban disparities in health-care personnel mirror disparities of both wealth and health. In 1992, the poorest districts in southern Africa reported 5.5 doctors, 188.1 nurses, and 0.5 pharmacists per 100,000 population. The same survey found, in the richest districts, 35.6 doctors, 375.3 nurses, and 5.4 pharmacists per 100,000 population.<sup>4</sup> Nearly 90% of Malawi’s population is rural, but over 95% of clinical officers were to be found in urban facilities; 47% of Malawi’s nurses were in tertiary care facilities.<sup>5</sup> Even community health workers, trained to provide first-line services to rural populations, often transfer to urban districts. In Kenya, for example, there were only 138 health workers per 100,000 persons in Kenya’s rural North Eastern Province in 1989 compared to 688 per 100,000 in Nairobi.<sup>6</sup>

In addition to inter- and intranational transfer of personnel, AIDS itself is contributing to personnel shortages across Africa. Although data on the prevalence of HIV among health professionals is scarce, the available numbers suggest substantial and adverse impacts on an already overburdened health sector. The situation in Malawi is instructive. For example,

\*The WHO estimates that there are only 27 physicians per 100,000 Haitians. The numbers within the country vary dramatically, with the highest numbers recorded in the area around the capital city. Rural regions, including Joseph’s home district (the Central Department), post the lowest coverage: In central Haiti, there are only 2 physicians per 100,000 population (Pan American Health Organization. Health Institutions and Human Resources in Haiti. Updated information as of March 2004. Available at: [www.paho.org/English/DD/PED/Health\\_institutions.ppt](http://www.paho.org/English/DD/PED/Health_institutions.ppt)).

**FIGURE 4-1** The “Lazarus effect”: Effective, accessible treatment for HIV and TB brought Joseph back from the brink of death. His experience, and that of hundreds of thousands of other impoverished patients in rural Haiti now receiving free medical care through a public-private partnership, is renewing his community’s faith in the health sector and restoring hope to the destitute sick everywhere. *A*, March 2003: Joseph, before treatment. *B*, September 2003: Joseph after treatment for HIV and TB, with his healthy niece. *C*, August 2004: Joseph speaks at a health and human rights conference. (*A* and *B*, by David Walton; *C*, by Joia Mukherjee. Copyright, Partners in Health. All rights reserved.)

a ranking cause of loss of health-care workers is premature death, often from AIDS.<sup>7</sup> In 1999, it was estimated that 17% to 32% of health-care workers in Botswana had HIV disease, a number expected to increase in the coming years.<sup>8</sup> A recent study that examined the fates of a small cohort of Ugandan physicians found that at least 22 of the 77 doctors who graduated from Makerere Medical School in 1984 had died by 2004, most presumably of AIDS.\* Similar numbers have been registered in South Africa, where a small study by the

\*Reliable information was obtained for 74 of the 77 graduates, 22 of whom were confirmed dead. “The presumed causes of death (death certificates were not available) were AIDS (11); suicide (six); road traffic injuries, hepatitis, and alcohol related disease (one each); and unknown (two). Five of the suicides were related to knowledge or fear of being HIV positive.” Dambisya Y: The fate and career destinations of doctors who qualified at Uganda’s Makerere Medical School in 1984: Retrospective cohort study. *BMJ* 329:600–601, 2004.

South African Human Sciences Research Council found that seroprevalence among health professionals was similar to that among the general population—in this case, 15.7% of all health-care workers surveyed.<sup>9</sup>

The shortage of empowered medical personnel in the areas hardest hit by HIV has profound implications for prevention and treatment efforts in these regions. The cycle of health sector impoverishment, brain drain, and consequent lack of personnel to fill positions, when they are available, conspires against ambitious programs to bring antiretroviral drugs to those living with both AIDS and poverty. The president of Botswana recently declared that one of his country's main obstacles to rapidly expanding HIV/AIDS treatment is "a dearth of doctors, nurses, pharmacists, and other health workers."<sup>10</sup> In South Africa, the departure of nearly 600 pharmacists in 2001, coupled with standing vacancies for 32,000 nurses, has put continued strain on that relatively affluent country's ability to respond to calls for expanded treatment programs.<sup>11,12</sup> In Malawi, only 28% of established nursing posts are filled.<sup>5</sup> Furthermore, the education of medical trainees is also jeopardized as the ranks of the health and academic communities continue to shrink due to migration or disease. The long-term implications are staggering.

A proper biosocial analysis of the brain drain reminds us that health personnel flight—almost always, as this review suggests, from poor to less-poor regions—is not simply a question of desire for more equitable remuneration. Epidemiologic trends and access to the tools of the trade are also relevant, as are working conditions in general. The advent of HIV has led, in many of the settings now losing skilled health personnel, to a sharp rise in tuberculosis incidence; other opportunistic infections have also become, in the eyes of providers, insuperable challenges. Together, these forces have conspired to render the provision of proper care impossible, as the comments of a Kenyan medical resident suggest: "Regarding HIV/AIDS, it is impossible to go home and forget about it. Even the simplest opportunistic infections we have no drugs for. Even if we do, there is only enough for a short course. It is impossible to forget about it...Just because of the numbers, I am afraid of going to the floors. It is a nightmare thinking of going to see the patients. You are afraid of the risk of infection, diarrhea, urine, vomit, blood....It is frightening to think about returning."<sup>13</sup>

Given the impossible situations under which these health-care personnel work, is it any surprise, then, when Randall Tobias, the U.S. government's appointed Global AIDS Coordinator, notes that there are more Ethiopian physicians practicing in Chicago than in all of Ethiopia?<sup>14</sup> In Zambia, only 50 of the 600 doctors trained since the country's independence in 1964 remain in their home country.<sup>12</sup> Nor is it surprising that a 1999 survey of medical students in Ghana in their final year of training revealed that 40 of 43 students planned to leave the country upon graduation.<sup>4</sup>

When providing care for the sick becomes a nightmare for those at the beginning of clinical training, physician "burnout" soon follows among those who carry on in settings of impoverishment. In the public-sector institutions put in place to care for the poorest, the confluence of epidemic disease, lack of resources with which to respond, and user fees

have led to widespread burn-out among health workers. Raviola and colleagues offer an important biosocial study linking epidemiology, the experience of providers, and an understanding of the political economy of the Kenyan health-care system. "I don't see a future for the medical profession here," concludes a resident at Kenyatta National Hospital in Nairobi. "Why? It is expensive. You have to invest a lot. There is no government support. People can't afford care here."<sup>13</sup>

In the resource-poor settings upon which this chapter has focused, medical personnel are often precisely those who would conduct research, whether biosocial or conventional, in tropical and infectious diseases. Nurses and other providers are of course similarly affected, but patients and their families are those who pay most dearly for provider burnout, just as they bear the burden of disease and, with the introduction of user fees, much of the cost of responding, however inadequately, to new epidemics and to persistent plagues.

### Structural Adjustment and Access to Care

The large-scale socioeconomic forces at work in the differential distribution of sickness and health often stem from decisions made far from hospital wards or even national capitals. Many African countries in fact registered improvements in health systems and indices in the years following independence. Kenya, for example, saw infant mortality decline by more than 58% between 1963 and the early 1990s.<sup>15</sup> However, the economic crises of the 1970s and 1980s left many of these postcolonial nations mired in mounting debts to offshore creditors. African governments needed loans to pay interest on the outstanding debts and to meet basic social spending needs. The World Bank and the International Monetary Fund became the principal creditors in this arena, and these institutions soon found themselves the chief sources of funding for health and development projects in poor countries. Loans came with strict requirements, however: the imposition of sweeping economic "reforms" in favor of a "free market" system designed to stimulate the economy and fix perceived imbalances in trade and government budgets. These economic austerity measures—termed "structural adjustment programs"—had profound and often deleterious effects on the health of many countries, as mandatory reductions of government budgets led to sharp declines in funding for the health sector. In Nigeria, for example, per capita expenditure on health care fell by more than 70% between 1980 and 1987.<sup>16</sup> Some have argued that structural adjustment programs in fact increased risks for HIV infection in Africa.<sup>17</sup>

Cuts in health-care spending led to the closing of public health posts, clinics, and hospitals in many parts of sub-Saharan Africa. Even basic services—from first-aid to prenatal care—were slashed from the operating budgets of many Ministries of Health. Between 1990 and 1992, 14 African countries—all mired in structural adjustment programs—saw at least a 10% decline in the level of polio vaccination. Botswana topped the list with a 24% reduction in polio vaccine coverage during this time.<sup>18</sup>

The collateral damage of economic austerity programs in sub-Saharan Africa also directly affected health-care

professionals. Thousands of doctors and nurses across the continent lost their jobs as a result of budget restructuring. Coupled with the brain drain phenomenon, the health sector was further decimated as skilled employees lost their jobs and emigrated overseas. Ghana saw its contingent of doctors more than halved between 1982 and 1992, from 1700 to fewer than 670.<sup>19</sup> In late 2003, an estimated 4000 Kenyan nurses were unemployed secondary to economic policies that restricted recruitment of health workers into the public sector.<sup>20</sup>

### User Fees

Another legacy of economic austerity programs is the widespread institution of “user fees” for health services that were formerly free of charge, with the intent of generating revenue for the health sector. Instead of revitalizing the health sector, however, user fees have often sharply reduced the ability of the poor to access medical care. In Ghana, Swaziland, and Congo—three of the first countries to implement user fees—data have shown that making the poor pay for care led to a marked reduction in the utilization of health services.<sup>21</sup>

In an effort to improve access to primary care, specifically maternal and child health, UNICEF and WHO introduced the Bamako Initiative in 1998, with the approval of the Health Ministries of the WHO African Region. The initiative includes the provision of generic essential drugs by donor agencies or national governments to district and village health management committees. These drugs are then sold to the public at a profit, which is then, theoretically, used to buy back the initial stock of drugs and to improve the quality of health centers. But despite widespread support from decision makers and a great deal of positive press, several studies have reported a decline in attendance rates for health services as a result of the user charges stipulated by the Bamako Initiative.<sup>22,23</sup> A longitudinal study conducted in Congo revealed a 40% decrease in health service utilization between 1987 and 1991 after the adoption of the Bamako Initiative.<sup>24</sup>

Similar declines in the utilization of health services after the introduction of cost-sharing were documented elsewhere in the region, including in Tanzania (where utilization of outpatient services in government district hospitals declined by more than 50%), Uganda, Swaziland, and Ghana.<sup>25–28</sup> Despite exemptions for children and the indigent, Mbugua and colleagues found that attendance at rural Kenyan government health facilities plummeted by 41% after user fees were introduced, and rebounded after fees were abolished.<sup>29</sup> In a cross-sectional study of 37 countries in sub-Saharan Africa, even the money-minded World Bank concluded that user fees decreased utilization of health services.<sup>30</sup> Another study revealed that the number of men reporting to sexually transmitted disease (STD) public clinics in Kenya fell by 40% after user charges were introduced in 1989; the authors concluded that the introduction of user fees in STD clinics likely increased the number of untreated STDs in the population.<sup>31</sup> This association has clear implications for HIV treatment and prevention efforts, as HIV is a sexually transmitted disease in much of the world.

### Economic Costs and Adherence to HIV Therapy

As HIV treatment programs in resource-poor settings undergo expansion, advocates and pundits alike agree that medication adherence is paramount to the success of these initiatives. But early data have already shown that adherence is significantly reduced in programs in which patients are forced to pay even nominal fees for their medications. Of 137 Ugandan patients being treated with antiretrovirals (ARVs), nearly 33% had dropped out of therapy within 38 weeks; many of them evidenced drug-resistant disease. The cost of therapy was the main reason cited by patients for poor adherence.<sup>32</sup> In Senegal, up until 2000 all patients were required to pay \$35 a month for antiretroviral treatment. Indigent patients were exempted from these fees in 2001, and in 2003 the government launched free antiretroviral treatment for all. In a study of adherence during this period, it was noted that over 50% of patients reporting treatment interruption for more than 5 days in 1999–2000 cited financial problems as the chief cause. By 2003, this percentage had dropped to 15%.<sup>33</sup>

Studies from other countries corroborate the negative effects of direct and indirect costs of antiretroviral therapy on adherence. In an analysis of barriers to antiretroviral adherence in Botswana, Weiser and colleagues revealed that nearly 50% of patients who self-reported poor adherence cited financial reasons as the most significant barrier. The authors advised that “patients in Botswana will achieve much higher adherence rates if structural and economic treatment barriers are minimized.”<sup>34</sup> These results are similar to those reported by researchers in Uganda, who concluded that “ability to purchase and secure a stable supply of therapy are major barriers to adherence.”<sup>35</sup> In Côte d’Ivoire, despite a UNAIDS HIV Drug Access Initiative and public subsidies, the poorest patients were precisely those who did not have access to ARVs.<sup>36</sup>

These studies suggest that charging for ARVs excludes the poor from access to care and also serves to increase the likelihood that acquired resistance will develop through inadequate therapy. In a recent editorial, Mukherjee concludes that “a human rights-based—rather than market-based—approach is the only realistic strategy for an epidemic that is concentrated in the poor and marginalized communities who have neither access to health care nor the ability to pay for treatment.”<sup>37</sup>

The economic toll of HIV before the patient is even diagnosed leads to further impoverishment and delays in seeking and receiving effective care. Lessons from the long-entrenched TB epidemic are instructive. In Bangladesh, where all TB services and medications are provided free of charge, the average total loss of income before proper diagnosis and treatment was estimated to be \$245, or nearly 4 months of a family’s yearly income.<sup>38</sup> Findings were similar in Zambia, where the indirect cost to patients prior to a TB diagnosis was almost 130% of their mean monthly income. These authors found that “most patients required significant financial assistance while seeking care for their disease-related symptoms.”<sup>39</sup> In war-torn Sierra Leone, Gibson and colleagues noted that the highest costs to patients were sustained prior to entry into a tuberculosis treatment program, highlighting the economic burden to the patient and family before a diagnosis is even obtained.<sup>40</sup> In Thailand, even after diagnosis at a

government hospital, 80% of patients incurred significant costs for travel and food during hospital visits. In the same study, up to 15% of patients were forced to sell household assets and use bank loans to cope with illness-related expenses.<sup>41</sup>

Travel to and from the clinic can exact a significant toll on patients and is an often-significant barrier to care, especially among the poor.<sup>42,43</sup> Data for TB have shown high travel costs to clinic are directly associated with poor compliance, as patients cannot afford regular transportation to pick up their medications every month.<sup>44</sup> These data have obvious implications for HIV treatment programs.

## Civil Conflict

The noxious synergy of civil strife and poverty has a well-documented negative impact on the health of the poor. Conflict contributes to the deterioration of existing public health infrastructure in addition to creating conditions that decrease access to clean water and shelter, which can in turn lead to increased incidence of infectious pathogens. Excess morbidity and mortality often result from a near-complete lack of basic health services in and around conflict zones.<sup>45</sup> In an editorial on the violence that engulfed Haiti in 2004, Farmer laments the near-total collapse of the health sector.<sup>46</sup> As easy targets for violence, as well as often being overwhelmed by the consequences of violence, hospitals are increasingly prone to acute staff shortages and stockouts of medications and supplies. The Port-au-Prince hospital—the only university teaching hospital, and the major provider of health care to the poor in the capital city—has been nonfunctional for months at the time of this writing.<sup>47</sup>

The direct impact of conflict on HIV and TB epidemics has also been documented. In Sierra Leone, 23% of tuberculosis clinics closed between 1990 and 1994 secondary to violence and war.<sup>40</sup> The Rwandan genocide in 1994 is believed to have contributed to the expansion of the HIV epidemic to rural areas of that country.<sup>48</sup>

## Stigma

The role of stigma as a major barrier to care for HIV patients has been extensively reviewed elsewhere.<sup>49–51</sup> However, recent experiences in resource-poor settings suggest that the introduction of effective HIV treatment and care programs can help destigmatize what was once considered a fatal disease.<sup>52</sup> In communities in rural Haiti, dramatic, visible recoveries after initiation of antiretroviral treatment, dubbed the “Lazarus effect,” have led to a sharp decline in HIV-related stigma.<sup>53</sup> While the contours of discrimination vary from country to country, AIDS-related stigma will likely decrease as access to treatment improves and as people come to realize that HIV is a manageable disease.

## THE COST OF MALARIA

Malaria's human toll is enormous. An estimated 250 million people suffer from malarial disease each year, and the disease annually kills between 1 million and 2.5 million people, mostly pregnant women and children under 5. The poor

disproportionately suffer the consequences of malaria. Fifty-eight percent of malaria mortality occurs in the poorest 20% of the world's population; 90% of malaria mortality is registered in sub-Saharan Africa.<sup>54</sup> The differential magnitude of this burden of mortality is greater than that associated with any other disease.<sup>55</sup> Malaria-associated morbidity is also higher, as documented in a study from Zambia which revealed a 40% greater prevalence of parasitemia in children under 5 in the poorest wealth quintile than in the richest.<sup>56</sup> Despite suffering the greatest consequences of malaria, the poor are precisely those least able to access effective prevention and treatment tools.

Economists describe the complex interactions between malaria and poverty from an opposite but complementary perspective: they delineate ways in which malaria arrests economic development both for individuals and for whole nations. Microeconomic analyses focusing on direct and indirect costs estimate that malaria may consume up to 10% of a household's annual income.<sup>57</sup> A Ghanaian study that categorized the population by income group highlighted the regressive nature of this cost: while the burden of malaria represents only 1% of wealthy families' income, 34% of a poor household's income is consumed by it.<sup>54</sup>

At the national level, macroeconomic analyses estimate that malaria may reduce the per-capita gross national product (GNP) of a disease-endemic country by 50% relative to a non-malarial country. The causes of this drag include high fertility rates, impaired cognitive development of children, decreased schooling, decreased saving, decreased foreign investment, and restriction of worker mobility.<sup>58</sup> Given this enormous cost, it is little wonder that an important review by Sachs and Malaney concludes that “where malaria prospers most, human societies have prospered least.”<sup>59</sup>

## Rolling Back Malaria

Due in part to differences in vector distribution and climate, resource-rich countries offer few blueprints for malaria control and treatment that are applicable in tropical settings. In 2001, African heads of state endorsed the WHO Roll Back Malaria (RBM) campaign, which prescribes strategies appropriate for sub-Saharan African countries. RBM recommends a three-pronged strategy to reduce malaria-related morbidity and mortality: the use of ITNs, combination antimalarial therapy, and indoor residual spraying.

Some RBM programs have had limited successes, but overall the burden of disease has continued to grow. In fact, annual malaria-attributable mortality increased between 1999 and 2003.<sup>60</sup> While the RBM's own *Africa Malaria Report 2003* is quick to note that morbidity and mortality data collection methods in sub-Saharan Africa are inadequate and indicators may thus lag behind actual outcomes of the ongoing campaigns, they nevertheless acknowledge that “RBM is acting against a background of increasing malaria burden.”

Limited success in scaling-up ITN coverage is indicative of the campaign's inadequate acknowledgment of the economic barriers that preclude the destitute sick from accessing critical preventive technologies. Despite proven efficacy and what are considered “reasonable costs,”\* the 2003 RBM report reveals disappointing levels of ITN coverage. Of 28 African countries

surveyed, only 1.3% (range, 0.2%–4.9%) of households owned at least one ITN, and less than 2% of children sleep under an ITN.<sup>54</sup> Why has the RBM campaign failed to achieve its goals? Do Africans not want to use bednets? Do they not recognize malaria as a health risk? Or have project managers and donors miscalculated most Africans' ability to obtain bednets?

The RBM strategy initially emphasized the importance of commercial markets as sources of ITNs for African populations.<sup>61</sup> A precedent supporting this emphasis is the prior existence in countries such as Madagascar and Mali of local markets for untreated bednets. Presumably, therefore, a demand for bednets existed prior to the RBM campaign, as did a distribution system with points of sale.<sup>62</sup> However, this market approach, even with the application of subsidized social marketing strategies, has not resulted in large increases in coverage in the first years of the RBM campaign.

Several studies have attempted to define willingness to pay (WTP) and actual payment for ITNs in African countries in order to understand why market-based strategies have been unsuccessful. Policy-makers often utilize WTP to determine appropriate pricing for social marketing projects and to project revenue and demand.<sup>63</sup> A cross-sectional study in a rural Nigerian community administered two questionnaires, 1 month apart, to examine community members' WTP for ITNs, actual purchase of ITNs (the second questionnaire was accompanied by the opportunity to buy a subsidized ITN), and factors (such as socioeconomic status and recent history of malarial illness) contributing to hypothetical and actual purchase ( $n = 453$  answering both surveys). The poorest quintile perceived a greater risk of malaria relative to the other quintiles (27.3% vs. 12.9%–21.6%,  $p < 0.05$ ). However, the poorest quintile was least likely to own a net, purchase a net, or express hypothetical WTP. Interestingly, even the most well-off quintile was willing to pay only 51% of the government-set price of the ITN. This finding suggests that even the relatively well-off may not be willing or able to pay for bednets at set prices. The authors of this study concluded that reliance on the sale of nets alone may prove inadequate and that further studies to define the degrees to which costs can be lowered and/or demand increased are needed.<sup>64</sup>

Guyatt and colleagues also offer a critique of the WTP methodology in highland Kenya. Their 2002 study compared the attitudes of people living in homesteads that had been provided with heavily subsidized ITNs ( $n = 190$ ) to households

that had no ITNs and had not been targeted by other health-care initiatives ( $n = 200$ ). Ninety-seven percent of all households expressed willingness to pay for ITNs. However, only 4% of those willing to pay offered spontaneously to meet the suggested price of 350 KSh (Kenyan shillings). After being prompted that "nets are expensive," 26% of respondents expressed willingness to pay the full price. This study did not actually offer nets for sale; therefore, the number of nets actually purchased cannot be compared. However, this study did contextualize the hypothetical WTP for ITNs by comparing it to other household costs: the price of an ITN equals the cost of sending three children to primary school for a year. In contextualizing the nets' relative cost, the authors call into question the likelihood that families in this district, over half of whom fall below the Kenyan poverty line, would actually be able to purchase ITNs.<sup>65</sup>

Given the documented barriers to purchasing ITNs, especially among the poorest of the poor, many researchers and development professionals involved in malaria programs have called for the free distribution of ITNs, stressing their importance as a public health measure: "the priority for Africa should be to adopt ITNs as a public good—like childhood vaccines."<sup>66</sup>

Adoption of free ITN distribution strategies have been limited, however, by concerns about their feasibility and about clients' misuse of the bednets (for example, as nets for fishing). Evidence from a targeted free distribution program discounts both concerns. In 2001, a Kenyan program sponsored by UNICEF sought to distribute 70,000 ITNs to pregnant women through antenatal clinics. Within 12 weeks, over 50% of the ITNs had reached their intended targets. A 1-year follow-up evaluation of 294 women who had received bednets while pregnant—152 women were from a high-transmission area and 142 from a low-transmission area—revealed that 84% of women in the high-transmission area used the nets throughout their pregnancy. One year later, 77% continued to use the bednets. In the low-transmission area, 57% of women used the bednets during their pregnancy, and 46% continued to use them a year later.<sup>67</sup> These results contradict suppositions that free nets may not be used because recipients do not value them.

Given the scope and magnitude of the challenge posed by malaria, it is unlikely that any one strategy will work for every region or population within a country or across the world. Encouraging results from an employer-based ITN distribution

\*ITNs have been proven to be an efficacious and cost-effective public health intervention. A meta-analysis of controlled trials indicates that malaria incidence is reduced by 50% in those who sleep under ITNs compared to those who do not use nets at all (Choi HW, Breman JG, Teutsch SM, et al: The effectiveness of insecticide impregnated bednets in reducing cases of malaria infection: A meta-analysis of published results. *Am J Trop Med Hyg* 52:377–382, 1995). Even when use of ITNs is compared to use of nontreated nets, the incidence of malaria is reduced by a quarter. On an individual level, the utility of ITNs extends beyond protection from malaria, as several studies suggest that all-cause mortality is reduced in children under 5 to a degree that is greater than the effect attributable to the reduction in malarial disease alone (Nuwaha F: The challenge of chloroquine-resistant malaria in sub-Saharan Africa. *Health Policy Plan* 16:1–12, 2001). Morbidity, specifically due to anemia, which predisposes children to diarrheal and respiratory illnesses and pregnant women to low-birth-weight infants, is also reduced in populations using ITNs (Bates I, Fenton C, Gruber J, et al: Vulnerability to malaria tuberculosis, an HIV/AIDS infection and disease. Part 1: Determinants operating at individual and household level. *Lancet Infect Dis* 4:267–277, 2004). In addition, ITNs provide a supplemental benefit in some areas by preventing transmission of lymphatic filariasis, cutaneous leishmaniasis, Chagas disease, and tickborne relapsing fever (Molyneux DH, Nantulya VM: Linking disease control programmes in rural Africa: A pro-poor strategy to reach Abuja targets and millenium development goals. *BMJ* 328:1129–1132, 2004). At the community level, investigators suggest that the use of an ITN in just one household may reduce the number of mosquito bites in households up to several hundred meters away (Curtis C, Maxwell C, Lemnge M, et al: Scaling-up coverage with insecticide-treated nets against malaria in Africa: Who should pay? *Lancet Infect Dis* 3:304–307, 2003). The cost of ITNs per disability-adjusted life year (DALY) saved is estimated at \$10 to \$38, which qualifies it as a "very efficient use of resources and [a] good candidate for public subsidy" (Nuwaha F: The challenge of chloroquine-resistant malaria in sub-Saharan Africa. *Health Policy Plan* 16:1–12, 2001).

system in Kenya highlight important successes of public-private partnerships, particularly those targeted at working people who have higher and more stable incomes than those in rural subsistence economies.<sup>68</sup> Potential synergies between measles vaccine campaigns and possibly with lymphatic filariasis eradication campaigns have been reported or suggested.<sup>69</sup> Concerns about discomfort associated with sleeping under ITNs or about insecticide toxicities must be addressed through educational campaigns.

The challenge of malaria control will continue to require careful study of appropriate prevention and treatment strategies in the context of our increasingly sophisticated molecular understanding of the pathogen, vector, and host. However, an appreciation for the economic and structural devastation wrought by malaria, like that by diarrhea, AIDS, and tuberculosis, on the most vulnerable populations should heighten our commitment to the critical analysis of how to implement proven strategies to prevent and treat these diseases.

### **HARNESSING SCIENCE TO CONTROL EPIDEMIC DISEASE: A BIOSOCIAL CHALLENGE**

All of what are now often considered tropical diseases—AIDS, African trypanosomiasis, dengue, leishmaniasis, malaria, schistosomiasis, TB, Chagas disease, lymphatic filariasis, and onchocerciasis—are more notable for their differences than for their similarities. Some are caused by viral pathogens; others by parasites or bacteria. Some are vector-borne; others have no known nonhuman hosts. Some of these infections are vaccine-preventable; for others, reliable prevention methods are still under development. While their efficacy varies widely, prevention and/or treatment options are available for each of these diseases. Why, then, do these infections remain ranking causes of death and debility in the 21st century?

In truth, the so-called “tropical” diseases are more linked to social and economic class than to latitude. Although new basic knowledge, especially if generated by “use-inspired basic research,”<sup>70</sup> will lead to improved diagnostic and therapeutic tools, and even as the pace of discovery increases due to our emerging understanding of the genomic structure of the pathogens and vectors in question, it is increasingly clear that social and economic barriers constitute formidable obstacles to the effective and equitable deployment of technologies new and old. As Farmer and Becerra wrote,

The phenomena that concern us—epidemic and endemic disease—are not solely biological; neither are they purely social. Yet conventional studies typically rely on disciplinary approaches and fail to reveal the full complexity of these epidemics. Only by embracing a transdisciplinary, biosocial approach can we hope to describe fully these “tropical” epidemics, and intervene successfully. For example, when yet another hydroelectric dam alters rates of schistosomiasis or filariasis, we must also study the “behavior” of policymakers at development agencies if we are to understand the distribution and outcome of schistosomiasis and filariasis. When recurrent drug stockouts characterize a tuberculosis control program, the “knowledge, attitudes, beliefs and practices” of patients may have only limited relevance to the emergence of drug resistance, whereas fluctuating drug prices, tariffs, and poor drug quality might prove determinant. When poor bloodscreening practices mean rising rates of American trypanosomiasis, it is an anthropology of blood banking and bloodbankers, rather than scrutiny of patients’ notions, that is called for.<sup>71</sup>

In seeking to understand the distribution and outcomes of infectious diseases in a broader social context, it is clear that a rising tide of social inequality is making it increasingly difficult to bring research to the bedside (in fact, many do not sleep in beds, but on mats or worse). This rising outcome gap may well prove the biggest challenge facing epidemic disease control in the coming decades. That is, as we develop new tools—vaccines and other preventives, diagnostics, and drugs—our failure to distribute them equitably means that the poor will do worse than ever. This has been seen starkly as regards TB, malaria, HIV, and other epidemics: although the diseases occur in many settings, virtually all deaths are registered among the poor. From an equity perspective, the situation has gotten worse since new tools were developed.

Not all the news is bad. Structural obstacles can be surmounted, as we saw in considering community-based care for AIDS in rural Haiti, based on previous successful efforts to treat tuberculosis in the same setting.<sup>72</sup> There have also been promising developments in the treatment of visceral leishmaniasis: an estimated 500,000 cases are diagnosed each year in India, Nepal, Bangladesh, East Africa, and parts of Brazil. Each of these settings is beset by socioeconomic barriers to care, and these barriers vary from site to site. In some places, health-care reform has weakened the public delivery systems. In others, such systems are absent or beyond the reach of the majority. But oral miltefosine, the first drug given “orphan” designation in Europe, is a relatively simple treatment and has proven effective in India,<sup>73</sup> where village health workers or mobile teams could administer the drug. It is hoped that miltefosine may also prove effective against post-kala-azar dermal leishmaniasis.

Malaria control, as noted, will require more basic science research. *Anopheles* genome sequencing and genetic manipulation for vector control are already well under way. Bioinformatics and applied genomics will help identify targets for new drugs, vaccines, and diagnostics. In some malaria-endemic areas, novel agents are already available to the fortunate few. The development and evaluation of new therapeutics—single-dose rectal artesunate and the combination pill Lapdap, consisting of two antifolate medications, chlorproguanil and dapsone—are now occurring in tandem with vector elimination campaigns. In KwaZulu Natal in South Africa, DDT reintroduction (indoor residual spraying), combined with the use of artemether-lumefantrine, dropped malaria cases dramatically. Without question, this represents a socially complex intervention that requires an understanding of local conditions and attitudes toward public health, insecticides, and tolerance of drugs with side effects.<sup>74</sup>

We conclude that a great deal more research is required if we are to have better diagnostics; more powerful, less toxic drugs; new control strategies; and effective vaccines for tropical diseases. Without a complementary analysis of social factors like those described in this chapter, however, the long-term deployment of old and new interventions to combat “tropical disease” will risk failure. In some cases, failure will simply maintain the alarmingly unequal topography of health-care outcomes around the globe, even for “easily treatable” diseases. However, as we have learned from the ravages of multidrug-resistant tuberculosis and malaria, failure is an unacceptable option: any efforts that result in failure exacerbate inequalities rather than diminish them, creating infections that are increasingly difficult to treat. Relinquishing our responsibility

to treat these diseases in poor people is not an option; rather, we must seek to understand social as well as molecular mechanisms of treatment failure. The social mechanisms may stem from problems with policy-making and implementation, but they will result in the development of resistance to drugs and insecticides, continued unacceptable rates of morbidity and mortality, and the persistence of pathogens that should be controlled thanks to the science of tropical medicine.

## ACKNOWLEDGMENT

The authors wish to acknowledge Alice Yang for her invaluable contributions to the conceptualization, research, and revision of this chapter.

## Nutrition and Micronutrients in Tropical Infectious Diseases

MARGARET KOSEK  
ROBERT E. BLACK  
GERALD T. KEUSCH

### INTRODUCTION

In addition to the toll in morbidity and mortality due to tropical infectious diseases, many infectious diseases common to all regions of the world last longer, are more clinically severe, and are more likely to have a fatal outcome in impoverished regions in the tropics because of the complex interactions between infection, protein-calorie malnutrition, and micronutrient deficiencies. The intent of this chapter is to provide insight into these interactions through a review of the supporting evidence linking the nutritional and micronutrient status of the host, the patency of the immune system, and the course and the outcome of infectious diseases of global importance. Although these interactions generally are accompanied by limited access to education, quality health care, and political instability, the interaction between nutrition and infection has immediate and direct adverse effects on health.

Despite modest improvements in indices during the past 15 years, protein energy malnutrition and micronutrient deficiencies remain highly prevalent in low- and middle-income countries. In 2000, the World Health Organization (WHO) estimated that 26.7% of children younger than the age of 5 years were underweight [weight for age Z (WAZ)  $< -2$ ], 32.5% were stunted (height for age Z  $< -2$ ), and 9.4% were wasted [weight for height Z (WHZ)  $< -2$ ].<sup>1</sup> Of the micronutrients with a demonstrated importance in determining the severity of infectious diseases, it is estimated that clinical vitamin A deficiency (xerophthalmia) affects 4.4 million preschool children and subclinical vitamin A deficiency affects another 127 million.<sup>2</sup> Iron deficiency and consequent anemia is detected in a high proportion of children and adults in developing countries.<sup>3</sup> Zinc deficiency is considered to be common in developing countries and estimates suggest that nearly all low- or middle-income countries have a moderate to high risk of zinc deficiency.<sup>4</sup> It is clear that in developing areas the interaction of malnutrition and infectious disease is a key determinant in health outcomes and an important factor in the transmission and ecology of infectious diseases.

### NUTRITION-INFECTION INTERACTIONS: PARADIGMS AND PRINCIPLES

In summarizing the experimental data for the interaction between malnutrition and infection in 1968, Scrimshaw et al. delineated three possible effects that may occur to varying degrees depending on the infectious agent and on the hosts' nutritional status: synergistic, antagonistic, or no effect.<sup>5</sup> The first, synergistic, occurs when the interaction of the infectious agent and nutritional deficiency results in a more adverse clinical outcome than the simple additive combination of the two conditions. This is easy to conceptualize: A malnourished child is more likely to die from a common intercurrent infection, such as pneumonia or dysentery, because of his or her weakened state than a well-nourished child. Alternatively, in more select cases the interaction between the malnutrition and the infection may be antagonistic. In this case, the combined effect of malnutrition and infection is less than expected because the infectious agent replication or pathogenicity is inhibited by the nutritional environment of the host. This may occur when the pathogen has greater requirements for or dependence on a metabolite than the host organism or when the pathology of the infection is dependent on host responses, such as inflammation, that are blunted by malnutrition. Lastly, there may exist circumstances in which the nutritional status of the host and the infectious agent do not interact and outcome is determined independently.

A guiding principle in the relationship between nutrition and infection has been the belief that dietary inadequacy both predisposes to infection and worsens outcome. This long-held principle suggests that nutritional interventions should play a critical role in thwarting the impact of infections. This view is based on observations such as the growth faltering in infants in developing countries that begins between 4 and 6 months of age. At this time, breast milk as an exclusive source of nutrition becomes increasingly inadequate for the growing infant, the available quantity of weaning foods is inadequate, protein content is low and of poor quality, and the availability of other key nutrients such as iron is substandard. Growth faltering in infancy, a good marker of nutritional deprivation,<sup>6</sup> is strongly associated with an increased incidence, duration, and severity of infectious diseases as revealed in numerous prospective studies carried out in areas with a high prevalence of malnutrition.<sup>7-9</sup> Cutaneous anergy was noted to be present in malnourished patients and led to the hypothesis that malnourished individuals suffered disproportionately from infectious diseases because of immune deficits. The relationship between adverse clinical outcomes and protein energy malnutrition is not limited to the developing world. There is a high prevalence of malnutrition in hospitalized adult patients (up to 50% in some studies)<sup>10,11</sup> on medical and surgical wards that is both underrecognized and undertreated by physicians.<sup>12</sup> Studies in these contexts reveal a poorer prognosis for those who are malnourished compared to well-nourished patients and demonstrate that surgical morbidity and mortality can be improved by nutritional rehabilitation prior to surgery.<sup>13-15</sup>

This principle led to attempts to minimize the impact of infectious diseases through food or nutrient supplements during the first year of life. Multiple planned interventions in the 1970s and 1980s sought to demonstrate that the provision of

more protein or limiting amino acids to the diet<sup>16,17</sup> and then more energy<sup>18</sup> (when the protein supplements failed to obtain the desired response) would reduce morbidity due to infectious diseases. However, prior to the dramatic success of supplementation with vitamin A in the 1990s interventions to curb the burden of infectious disease through nutritional supplementation were not clear successes.

Concurrent studies also took increasing note that kwashiorkor, the most severe form of protein energy malnutrition, was often preceded by an infection such as acute diarrheal disease,<sup>19</sup> measles,<sup>20</sup> or chicken pox.<sup>21</sup> Prospective birth cohort studies revealed that breast-fed children in impoverished settings grew in parallel to children in industrialized settings. However, when weaning foods were introduced and the incidence of both diarrhea and respiratory illness increased, growth faltering occurred. Even asymptomatic gastrointestinal infections led to growth faltering.<sup>5</sup> Measured observations of children during infectious disease episodes showed that common infections led to anorexia, nutrient malabsorption, micronutrient wasting, and growth deficits.<sup>22–27</sup> Diverse infections often occurred at a rate that continually delayed the ability of a child to achieve adequate catch-up in nutritional status or linear growth, and the child entered a cycle of infections and worsening nutritional status that in the worst cases progressed to kwashiorkor and death.

These observations taken together led to the current thinking of the relationship between nutritional status and infection as bidirectional. Not only could protein energy malnutrition or micronutrient deficiencies worsen infectious disease morbidity but also infections could, through metabolic alterations, lead to deterioration in nutritional and micronutrient status (Fig. 5-1). To maximally diminish the burden of infectious disease in malnourished populations, disease control

measures must be instituted in parallel with appropriately targeted nutritional interventions.

## EFFECTS OF MALNUTRITION ON INFECTION

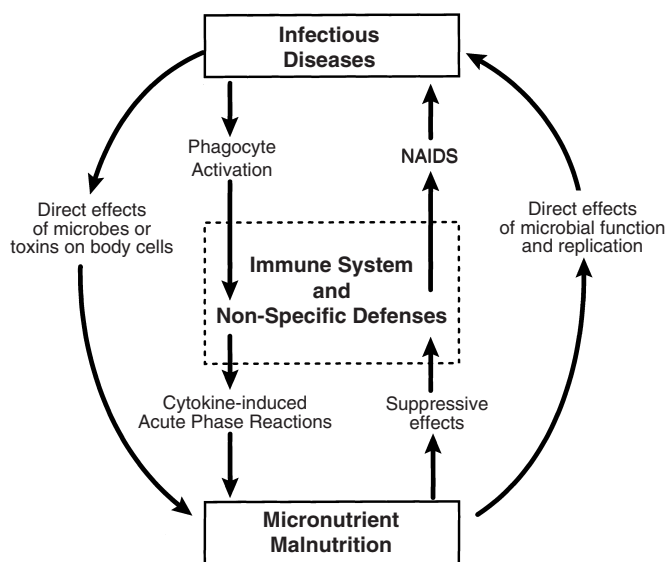

### Protein Energy

The degree to which the previous interactions occur and the extent of their actual impact gained clarity when several prospective community-based studies accurately characterized the relationship between anthropometrics and child mortality rates. By analyzing six of the most homogeneous of these studies, Pelletier et al. were able to detect a consistent relationship between the height-for-age index and the relative risk for mortality in under fives.<sup>28,29</sup> Child mortality increased at a compound rate of  $5.5 \pm 0.8\%$  for each decrement of 0.1 Z score units less than -1. Although a severely malnourished child (with a weight for age of <60% of the reference median or a WAZ of <-3) had 8.4 times the risk of dying as a non-underweight child in the same community, even mild malnutrition (with a weight for age of 70–79% or a WAZ between -1 and -2) had a relative risk of 2.5. This relationship between weight for age and mortality demonstrated consistent accuracy across study sites despite the presence of different pathogens and different rates of stunting and wasting. This relationship was the basis of the population associated risk statistic, a predictive model that inputs the prevalence of weight for age and calculates a percentage of child deaths associated with malnutrition based on the described relationship between WAZ and child mortality.<sup>30</sup> When this model was applied to 53 countries for which reliable anthropometric data were available, it was estimated that 56% of child deaths were attributable to malnutrition's potentiating effects of infectious disease morbidity (Fig. 5-2). Furthermore, because of the high prevalence of mild to moderate malnutrition, 83% of the deaths associated with malnutrition were attributed to mild to moderate, as opposed to severe, malnutrition (Box 5-1).

These findings have been replicated for all-cause child mortality and extended to cause-specific mortality.<sup>31</sup> In these new analyses, 53% of all deaths were attributable to underweight as an underlying cause. Likewise, 61% of diarrhea deaths, 57% of malaria deaths, 52% of pneumonia deaths, and 45% of measles deaths could be attributed to underweight status.

### Micronutrients

Micronutrients may have direct effects on the progression of an infection. The availability of key micronutrients in tissues or fluids can influence the growth and replication of infectious agents. For example, iron is required for the propagation of malaria and salmonella, and vitamin B<sub>12</sub> is required for *Diphyllobothrium latum*. More frequently, micronutrients mediate their effect on morbidity from infectious disease by modulating the immune system. A particular micronutrient deficiency rarely occurs in an isolated manner but often overlaps with other micronutrient deficiencies and protein energy malnutrition. Nevertheless, large prospective field trials have demonstrated the benefits derived from dietary supplements with vitamin A and zinc, which have been shown to reduce the incidence, severity, and duration of various infectious diseases. Data are more limited for iron, vitamin C, and selenium,

**FIGURE 5-1** A schematic representation of the interactions between infectious diseases and malnutrition. These two-way interactions between infectious disease and malnutrition include direct consequences of the infecting microorganisms and indirect (or secondary) effects that involve the immune system and other antigen-nonspecific host defensive organisms. NAIDS, nutritionally acquired immune dysfunction syndromes.

although in experimental contexts all have shown benefits. Each micronutrient has a specific role in the maintenance of a viable innate and/or adaptive immune response to potential pathogens. Micronutrients with a role in protein synthesis (e.g., thiamine, riboflavin, pantothenic acid, and essential amino acids) are all needed for the production of antibodies. The nonessential amino acids arginine and glutamine appear to provide important benefits for antigen-specific immunity and improved mucosal integrity,<sup>32</sup> and essential polyunsaturated fatty acids are needed to produce prostaglandins, lipoxins,

**FIGURE 5-2** Population attributable risk (PAR) for child deaths in 52 developing countries due to interactions between mild to moderate malnutrition (PAR: MMM; gray bars) or severe malnutrition (PAR: Severe; black bars) and infection, reported as the percentage of childhood deaths in each country. (From Pelletier DL, Frongillo EA, Schroeder DG, et al: The effects of malnutrition on child mortality in developing countries. *Bull WHO* 73:443–448, 1995.)

### Box 5-1 General Effects of Malnutrition on the Immune System

#### Protein energy malnutrition

- Decreased mucosal integrity
- Impeded macrophage migration
- Diminished T lymphocyte help in immune responses dependent on mature CD4 cells (cell-mediated immunity)
- Delayed kinetics and deficient antibody responses to certain antigens, particularly polysaccharide
- Depressed amounts of mucosal secretory IgA and specific secretory IgA antibodies in response to mucosal infections
- In vivo consumption of complement, depressed plasma levels of most complement components and activities effecting both alternate and classic pathways of complement activation
- Deficient serum opsonic activity
- ? favors type 2 response

#### Vitamin A deficiency

- Decreased mucosal integrity
- Altered cytokine expression leads to type 1 immune responses

#### Zinc deficiency

- Decreased macrophage chemotaxis
- Decreased neutrophil activity
- Decreased T cell response to antigen stimulation
- Favors type 2 responses
- Diminished opsonin activity

#### Iron deficiency

- Decreased neutrophil chemotaxis and bacteriocidal effects

and thromboxanes. This review is limited to vitamin A, zinc, iron, vitamin C, and selenium because data in these areas are more complete (Table 5-1).

### Vitamin A

Vitamin A modifies the severity of infectious diseases with profound effects on childhood mortality.<sup>33,34</sup> Childhood xerophthalmia, the most reliable indicator of vitamin A deficiency, is linked to a higher risk of morbidity and mortality. Severe untreated xerophthalmia (with corneal involvement) has a high risk of concomitant morbidity, malnutrition, and mortality, with case fatality rates for severe infections ranging from 5% to more than 50%.<sup>35</sup> Milder, noncorneal xerophthalmia, although not blinding, also increases the risk of morbidity and death. Preschool Indonesian children with night blindness (XN), Bitot's spots (X1B), or both conditions (representing "mild xerophthalmia") were three, six, and nine times more likely to die, respectively, within 3 months after diagnosis than their nonxerophthalmic peers.<sup>33</sup> The association was strong and consistent across age, illness, and anthropometric data suggesting a causal role of vitamin A deficiency in exaggerating the risk of early childhood mortality. Excess mortality also extended to siblings of xerophthalmic children. In Nepal, siblings of children with XN or X1B were at 2 or 3 times higher risk of death than children in households with no xerophthalmia.<sup>36</sup> Xerophthalmic "clusters" occur within households, with case siblings being 7 to 13 times more likely to have, or develop, xerophthalmia than children in

**Table 5-1** Micronutrient Requirements

	Normal Blood Levels	Treatment (Replacement) Dose	Maintenance Dose or RDA	Symptoms and Signs of Deficiency	Deficiency Effects on Host Defenses	Risk of Toxicity
Vitamin A	25–94 µg/dL	200,000 IU (60,000 RE)* PO qd × 2, at 4 wk, then q 4–6 mo (½ if <12 mo old) or 2440 RE q wk	400–1000 RE/day (1600–5000 IU/day)	Xerophthalmia (night blindness [XN], Bitot's spots [XIB], corneal xerosis, and ulceration necrosis) More severe infections Increased mortality Scurvy (perifollicular hemorrhage, weakness)	Lymphoid tissue atrophy with dysfunction of T cells and cell-mediated immunity Impaired antibody production Impaired phagocyte mobility Impaired phagocytosis Impaired antioxidant activity	Skin scaling, headaches, papilledema, lymphadenopathy, hyperostosis, congenital malformations with ≥50,000 IU/day in early pregnancy Abdominal pain, diarrhea, false-negative stool guaiac, urine glucose
Vitamin C	>0.15 mg/dL (>300 mg stores)	100–200 mg/day	10–60 mg/day			
B-complex vitamins Thiamine (B <sub>1</sub> )	RBC transketolase coefficient <15%	50–100 mg IM or 15–30 mg/day PO	0.3–1.5 mg/day	Beriberi, Wernicke– Korsakoff dementia, nystagmus, ophthalmoplegia Cheilostomatitis	Impaired antibody production	Rare
B <sub>2</sub> (riboflavin)	FAD activity coefficient <1.2	10–15 mg/day PO	0.4–1.7 mg/day		Impaired antibody production	None known
Niacin (nicotinamide and nicotinic acid)	Low urinary N-methyl nicotinamide	50–150 mg nicotinamide (60 mg tryptophan → 1 mg niacin)	6–20 mg/day	Pellagra (dermatitis, diarrhea, dementia, death)	Impaired antibody production	Flushing, dry skin, hepatotoxicity with ≥3 g/day
B <sub>6</sub> (pyridoxine) <sup>†</sup>	>50 ng/mL	5–200 mg/day	0.5–3.0 mg/day	Diarrhea, anemia, seizures	Lymphoid tissue atrophy Impaired humoral and cell-mediated immunity	Sensory neuropathy with >500 mg/day
Folate	4–20 ng/mL	0.4–5.0 mg/day	30–400 µg/day	Macrocytic anemia	Lymphoid tissue atrophy Impaired humoral and cell-mediated immunity	May mask B <sub>12</sub> deficiency
B <sub>12</sub>	200–900 pg/mL	100 µg/day cyanocobalamin	0.5–4.0 µg/day	Macrocytic anemia, neuropathy, dementia	Dysfunction of lymphocytes and phagocytes	Rare
Vitamin D <sub>3</sub>	Variable (osteomalacia)	2999–4000 IU/day	200–400 IU/day (5–15 mg/day)	Rickets		Hypercalcemia, weakness

*Continued*

Table 5-1 Micronutrient Requirements—Cont'd

	Normal Blood Levels	Treatment (Replacement) Dose	Maintenance Dose or RDA	Symptoms and Signs of Deficiency	Deficiency Effects on Host Defenses	Risk of Toxicity
Vitamin E	>0.5 mg/dL	30–100 IU (mg) DL- $\alpha$ -tocopherol	6–30 IU mg/day	?Abortion ?Muscular dystrophy	Impaired humoral and cell-mediated immunity Impaired antioxidant activity	Nausea, diarrhea, $\uparrow$ bleeding with warfarin sodium with >1 g/day
Vitamin K Zinc <sup>‡</sup>	Normal clotting 70–130 $\mu$ g/dL	500 $\mu$ g/day 5 mg tid Zn acetate (15 mg/day $\times$ 7 days) = 3.9 mg elemental zinc/day 20 mg elemental zinc/day as zinc gluconate	12–140 $\mu$ g/day 5–15 mg/day	Bleeding Dermatitis and enteropathy Increased morbidity (duration) of diarrheal illnesses	Lymphoid tissue atrophy, with dysfunction of T cells and cell-mediated immunity Impaired antibody production Thymic hormone deficiency	?Hemolysis Hepatocellular damage and fibrosis Immunologic impairments
Iron	50–170 $\mu$ g/dL	40–80 mg Fe bid/tid	8–18 mg/day, 30 mg/day in pregnancy	Hypochromic, microcytic anemia	Impaired lymphocyte function Impaired bactericidal function	Hemochromatosis, cirrhosis
Iodine	Urinary 10 $\mu$ g/dL	150 $\mu$ g/day	40–150 $\mu$ g/day	Goiter, hypothyroidism	Delayed antibody production	Iodine-induced hyperthyroidism; <i>rarely</i> hypersensitivity
Copper	1.1 $\mu$ g/mL	2–4 mg/day	1.2–2.0 mg/day	Menkes' disease Anemia, bleeding, depigmentation, kinky hair, brain damage, low plasma ceruloplasmin	Impaired lymphocyte and phagocyte functions	Wilson's disease Cirrhosis, impaired metabolism of Fe and Zn
Selenium	100–130 ng/mL	100 $\mu$ g/day	10–70 $\mu$ g/day	Keshan's disease Cardiomyopathy, growth retardation, cataracts, impaired sperm production and glutathione peroxidase activity Increased risk of cancer	Impaired lymphocyte and phagocyte functions Impaired antioxidant activity	Damage to liver, brain, heart, and muscle

FAD, flavin adenine dinucleotide; IM, intramuscularly; PO, by mouth; RBC, red blood cell; RDA, recommended daily allowance.

\*RE (retinol equivalent) = 1  $\mu$ g (or 3.33 IU) retinol = 6  $\mu$ g (or 10 IU) beta-carotene.<sup>†</sup>Pyridoxal phosphate complexes with the antituberculosis drugs isoniazid and cycloserine.<sup>‡</sup>Zinc deficiency impairs release of retinol binding protein from liver and impairs retinol conversion to retinal (hence amplifying vitamin A deficiency).

xerophthalmia-free households.<sup>37</sup> This concentration of risk extends to the community: Children living in the vicinity of a xerophthalmic child are more than twice as likely to develop xerophthalmia,<sup>37</sup> and they may also incur a 30% higher risk of mortality than children living in communities virtually free of xerophthalmia.<sup>38</sup>

Intervention trials suggest that vitamin A supplementation modifies the severity, more than the incidence, of certain infectious diseases, as is the general trend with other forms of malnutrition. This effect is most apparent from its impact on all-cause mortality among preschool children. The initial trial conducted in Indonesia found that 1- to 6-year-old children receiving 60,000  $\mu\text{g}$  retinal equivalents (REs) of vitamin A every 6 months died at a 34% lower rate than children in villages not receiving supplements.<sup>39</sup> Seven subsequent trials in Asia and Africa provided vitamin A as a large oral dose (60,000  $\mu\text{g}$ ; half dose for children younger than 12 months of age) every 4 to 6 months, a weekly dose of 2440  $\mu\text{g}$ , or half a recommended daily allowance through fortified monosodium glutamate (a popular flavor enhancer). Five trials showed significant reductions in the mortality of children 6 or more months of age, ranging from 19% in Ghana to 54% in southern India,<sup>35</sup> whereas two trials failed to show an impact on mortality. A meta-analysis of these trials revealed a mortality reduction of 23% in all countries and 34% in Asia associated with the use of vitamin A in children older than the age of 6 months.<sup>35</sup> The effect of vitamin A supplementation given earlier than 6 months of age remains controversial.<sup>40–42</sup> However, in 1999, it was estimated that 97 million doses of vitamin A were given, and assuming the all-cause mortality was decreased by 23% in the treated populations, it is estimated that vitamin A supplementation prevented 242,000 deaths in that year alone.<sup>43</sup>

One of the clearest synergistic relationships of a micronutrient and infection is that of vitamin A and measles. Vitamin A treatment can profoundly decrease the morbidity, incidence of secondary complications, and mortality in children with measles. Although the degree of reduction has varied in trials using different doses, a meta-analysis found that the results of randomized controlled trials giving two doses of 200,000 IU vitamin A revealed an overall reduction in all-cause mortality of 67%.<sup>44</sup> The effect of vitamin A on all-cause mortality was greatest in children younger than the age of 2 years, where the decrease in all-cause mortality was 83%.<sup>45</sup> Furthermore, there was a 47% reduction in the incidence of croup and a 77% reduction in pneumonia-specific mortality, and the duration of diarrheal episodes was significantly shortened in the supplemented groups. Vitamin A supplementation is now recommended as standard of care treatment for measles in both developing and developed countries.

The measured impact of the effect of vitamin A for the primary prevention and treatment of diarrhea and respiratory tract infections yields conflicting findings. Several studies have noted a decrease in the duration and severity of diarrheal disease in children receiving vitamin A as primary prophylaxis.<sup>46,47</sup> In children with severe malnutrition and edema, low-dose daily vitamin A supplementation decreased the incidence of diarrhea by 89% (RR = 0.21; 95% CI, 0.07–0.62),<sup>48</sup> and in shigellosis one dose of vitamin A has been shown to increase the percentage of children achieving clinical cure at day 5 following treatment.<sup>49</sup> However, in a meta-analysis of eight double-blind

randomized controlled trials of vitamin A prophylaxis no effect on diarrheal disease incidence was found and a mild negative effect (RR = 1.07; 95% CI, 1.02–1.12) was noted on the incidence of respiratory disease.<sup>50</sup> Additionally, vitamin A given as adjunctive therapy in children hospitalized with pneumonia was associated with a decreased oxygen saturation and increased respiratory distress in Peru,<sup>51</sup> and there was a nonsignificant trend toward higher mortality in vitamin A-supplemented children hospitalized with pneumonia in Tanzania.<sup>52</sup>

Children with xerophthalmia or severe malnutrition or any child with measles should be treated according to guidelines from WHO: 200,000 IU of vitamin A orally on presentation, 200,000 IU the following day, and another 200,000 IU dose 2 to 4 weeks following the infection to reestablish liver stores. Children younger than the age of 1 year should receive half doses. The use of vitamin A as routine adjunctive therapy for respiratory infections and diarrhea is not indicated.

## Zinc

The classical syndrome of zinc deficiency seen in acrodermatitis enteropathica, a rare genetic disorder, is characterized by dermatitis, linear growth deficits, anorexia, irritability, and chronic diarrhea. Despite the lack of a reliable and widely used indicator of zinc status with which to base estimates of prevalence of this condition, the clinical trials of supplementation showing significant and large impacts on common child diseases in diverse geographic zones and populations indicate that zinc deficiency is a common condition in children in developing regions.<sup>53</sup> Zinc supplementation has been shown to be effective for the primary prevention of diarrhea, respiratory tract infections, and malaria, and trials have indicated a role for zinc in the adjunctive treatment of diarrhea and respiratory tract infections. Trials have demonstrated that zinc-supplemented children have lower mortality and large trials are under way to assess this outcome.

There are 13 studies available that evaluated zinc supplementation as a primary preventive strategy for diarrheal disease in preschool children.<sup>54–67</sup> In 8 of these studies, zinc therapy had a statistically significant protective effect that ranged between 12% and 69%, and in no study was zinc supplementation associated with an increase in the risk of diarrheal illness. A pooled analysis containing the majority of these studies revealed an 18% (95% CI, 7–28) reduction in the incidence of diarrheal disease in supplemented children.<sup>68</sup> Additionally, a study of maternal zinc supplementation during the second and third trimesters of pregnancy noted a 16% decrease in the incidence of diarrhea and a 64% decrease in the incidence of dysentery during the first 6 months of life in children with low birth weights (<2.5 kg).<sup>69</sup> Populations in which plasma zinc concentrations were <9.8  $\mu\text{mol/L}$ , low birth weight or small for gestational age children, and children in the second year of life appear to experience the greatest benefit from zinc supplementation.

A meta-analysis has been performed on 12 studies with data regarding the efficacy of zinc in the treatment of diarrheal disease—5 regarding persistent diarrhea<sup>61,70–73</sup> and 7 regarding acute diarrheal disease.<sup>69–80</sup> For the persistent diarrhea trials, there was a reduction in the duration of illness and a 42% (95% CI, 10–63%) reduction in the composite variable of treatment failure or death in children receiving zinc.<sup>81</sup> WHO recommends

the use of zinc along with other vitamins and minerals in cases of persistent diarrhea. Children younger than 12 months of age, males, and children with wasting (WHZ <2) exhibited the greatest treatment benefit. In trials of zinc supplementation in acute diarrhea, the meta-analysis demonstrated that zinc significantly reduced diarrheal duration.<sup>81</sup> There is a WHO UNICEF recommendation that zinc supplements should be used in the treatment of acute diarrhea along with oral rehydration therapy.<sup>82</sup>

There are eight studies that evaluate the role of zinc in the primary prevention of respiratory disease.<sup>54–56,60,61,83</sup> Five of the eight studies reported a decrease in the incidence of acute respiratory tract infections and the protective effect reached significance in three of these studies. No studies reported an increase of respiratory tract infections associated with zinc supplementation. The protective effect ranged from 15% to 88% in the different trials, and a pooled analysis of the majority of these trial estimated a protective effect of 41% (95% CI, 17–59).<sup>68</sup> A trial of zinc as adjunctive therapy in severe acute lower respiratory tract infections in children younger than 2 years of age in Kolkata showed a decreased duration of fever and severity of illness scores in boys but not in girls.<sup>84</sup> This study found no benefit of vitamin A. Another randomized, controlled trial of zinc supplementation as adjunctive therapy of severe pneumonia has shown a significant benefit on recovery.<sup>85</sup>

Findings from three studies on the utility of zinc supplementation for the primary prevention of falciparum malaria are more conflicting. In the Gambia<sup>86</sup> and Papua New Guinea,<sup>59</sup> small studies revealed reductions in health center attendance attributable to falciparum malaria by 30% and 38%, respectively, although only the latter reached statistical significance. In Burkina Faso, a larger study found no difference in the incidence of falciparum malaria diagnosed by active surveillance in zinc-supplemented children. A multicenter trial<sup>87</sup> in Ecuador, Ghana, Tanzania, Uganda, and Zambia revealed no difference in time to reduction of fever or anemia in children receiving zinc as an adjunctive therapy for falciparum malaria.

Zinc given in addition to standard nutritional therapy was associated with lower incidences of morbidity for diarrhea and all-cause mortality in children with severe protein energy malnutrition (PEM).<sup>88</sup> It is clear that zinc, by diminishing the severity of the most prevalent causes of morbidity and mortality of children in developing regions, has an important and as yet unrealized potential to improve global child health. Because supplementation must be at least weekly, the application of this intervention will not be as easy as providing high-dose vitamin A every 6 months. Alternative approaches for primary prevention include supplementing basic foodstuffs or the promotion of the use of animal-based protein, which is a good source of zinc.<sup>89,90</sup> To promote the widespread use of zinc therapy for diarrhea, possible approaches include its incorporation into oral rehydration salts or an active distribution and education campaign of health care providers.

## Iron

Iron deficiency, with related anemia, is the most commonly identified micronutrient deficiency globally.<sup>3</sup> Dietary intakes in tropical zones are generally marginal and often confounded by blood loss associated with menstruation or infection with hookworm or schistosomes. Anemia, the most

**Table 5-2 Iron Deficiency Anemia Versus the Anemia of Infection**

Variable	Iron Deficiency Anemia	Anemia of Infection*
Red blood cell count	Depressed	Depressed
Hemoglobin	Depressed	Depressed
Hematocrit	Depressed	Depressed
Plasma iron	Depressed	<i>Markedly depressed</i>
Plasma transferrin	Markedly elevated	<i>Normal or depressed</i>
Transferrin saturation	Markedly reduced	Reduced
Plasma ferritin	Markedly reduced	<i>Normal or increased</i>
Tissue iron stores	Markedly reduced	<i>Normal or increased</i>
Iron therapy	Corrects the anemia	<i>Fails to correct the anemia</i>

\*Key differences are in *italics*.

recognizable indicator, may be either a symptom of nutritional deficiency or a response to active infection. Both iron deficiency anemia and the anemia induced by infection lower serum iron levels and therefore may alter the outcome of infections. Many iron intervention studies have been performed since the 1920s and they are well summarized in a review.<sup>91</sup> The analysis of findings is complicated by several factors. The first is the definition of anemia and the failure of many investigators to distinguish between iron deficiency anemia, anemia resulting from infection, and the hereditary hemoglobinopathies (Table 5-2). Furthermore, many studies, especially in the 1970s, were done with parenteral iron dextran as opposed to more physiologic daily oral supplementation. Nevertheless, supplementation with oral iron has been shown to increase hemoglobin and to reduce severe anemia, even in areas with endemic malaria.

Review of trials of iron supplementation indicated that provision of iron results in an increased density of malaria parasites in the blood and possibly clinical malaria.<sup>91</sup> The possible antagonistic relationship for the host between plasmodia and iron is further supported by the efficacy of iron chelators as adjunctive therapy in malaria.<sup>92</sup> A meta-analysis of iron supplementation trials found that iron-supplemented children have more diarrhea.<sup>93</sup> An enteric pathogen that appears to have a complex and possibly antagonistic relation with iron is salmonella. Experimental infection studies in rats have demonstrated both that severe iron deficiency enhanced resistance to infection and that mild deficiency enhanced susceptibility.<sup>94,95</sup> This may explain disparate findings from often cited observational studies that salmonella infections in Guam were often associated with iron-supplemented formula.<sup>96</sup> In general, iron supplementation has not been shown to either increase or decrease the risk of lower respiratory infections.<sup>92</sup>

## Vitamin C

Vitamin C decreases the duration but not the incidence of the common cold under normal conditions.<sup>97</sup> However, people undergoing strenuous activity who take vitamin C have been shown to have a decreased incidence of cold symptoms.<sup>98</sup>

## Selenium

One of the most novel observations regarding the interaction between a host and an infectious agent came from investigations into the origin and pathogenesis of Keshan's disease, an epidemic cardiomyopathy in China.<sup>99</sup> Epidemiologic investigations revealed that only populations living in areas with selenium-deficient soils developed the disease.<sup>100</sup> Subsequently, blood and tissue samples from cases revealed coxsackie viruses.<sup>101</sup> Laboratory mice fed on selenium-sufficient diets could be infected with a strain of coxsackie virus B4 and developed only mild limited cardiomyopathy, whereas selenium-deficient animals developed a severe cardiomyopathy upon infection with the same coxsackie virus B4 strain.<sup>102</sup> Although this is consistent with Scrimshaw's model of synergistic effects, it was subsequently noted that coxsackie viruses that did not normally exhibit cardiotoxicity in selenium-sufficient animals became cardiotoxic following the passage through selenium-deficient animals. Viral sequencing of the virus after passage through selenium-deficient animals confirmed genotypic changes, whereas strains passed exclusively through selenium-replete animals had no genotypic changes.<sup>103</sup> This appears to be an example of a novel type of interaction between host and infectious agent in which the infectious agent increases in virulence because of a specific deficit in the host's nutritional status. Similar findings were reported by the same group in a murine model of influenza A infection.<sup>104</sup> The extent to which the phenomenon of host nutritional status permanently increasing pathogen virulence occurs in nature is unclear, although it is hypothesized to be limited to RNA viruses.

## INFECTION-RELATED METABOLIC ALTERATIONS COMPROMISE HOST NUTRITIONAL STATUS

Infectious diseases may produce primary direct losses of body nutrients or secondary losses mediated through the inflammatory cytokine response and catabolic effects (Box 5-2). Loss of iron due to hookworm and schistosomes and loss of macronutrients from geohelminths illustrate the consequences of infectious agents. Direct losses may also result from toxins produced by the pathogen, such as toxigenic strains of

enteropathogens that result in sizable losses of electrolytes, water, and bicarbonate. Despite these important examples of direct effects, indirect effects account for the majority of the effects of pathogens on the host's nutritional status. There is an innate link between the immune and endocrine systems, and the metabolic changes associated with even mild infections can have an important effect on the nutritional status of the host. The inflammatory response induces constitutional symptoms, alteration in the metabolism of proteins and carbohydrates, and redistribution of minerals between physiologic compartments.

## Constitutional Symptoms

Constitutional symptoms are a common manifestation of fever, anorexia, malaise, headache, and myalgia. The first two have clear effects on the nutritional status of the host. The hallmark sign of infection, fever, is induced by the release of interleukin-1 (IL-1), IL-6, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), which act at the level of the hypothalamus to alter the temperature set point. This host response is believed to be a favorable adaptive response, but it comes at a substantial metabolic cost. For the augmentation of body temperature by 1°C, the basal metabolic rate increases by 12% to 23%.<sup>105</sup> Therefore, with a fever of 40°C, the basal metabolic rate increases approximately 30% to 60% over baseline needs.

Fever is generally accompanied by anorexia. Although the reason for this host response is not clear, its effects can be important. In a well-controlled study in Bangladesh, 41 children with diarrhea between 6 and 35 months of age and an age-matched control group were studied. It was found that children hospitalized with acute watery diarrhea, despite an educational intervention and "coaching," consumed only 47% to 58% of the total calories consumed by the healthy control group. Breast-feeding abrogated the changes to a large extent but not completely. Despite the provision of a nutritionally and culturally appropriate weaning food, the protein intake in normal breast-fed children was 2.5 times that consumed by completely weaned children with diarrhea.<sup>106</sup>

## Alterations in Protein Metabolism

Protein catabolism occurs even in subclinical infections.<sup>107,108</sup> Cytokine release triggers skeletal muscle proteolysis via increased levels of corticosteroids by the ubiquitin proteasome pathway,<sup>109,110</sup> and liberated amino acids are taken up in part by the liver, where IL-6-mediated transcriptional regulation leads to the enhancement of transcription and translation of essential acute phase proteins such as C-reactive protein, complement, serum amyloid, and  $\alpha$ -antitrypsin while down-regulating synthesis of exported proteins such as albumin and transferrin.<sup>111-113</sup> Despite active proteolysis of muscle, serum amino acids levels are lower than at steady state because of rapid uptake by the liver and immune cells.<sup>114</sup>

Not all amino acids released by proteolysis are recycled; branched amino acids, for example, are used for energy and the released nitrogen is excreted in the urine. Some amino acids, such as phenylalanine, are not recyclable and are also excreted in the urine. The loss of protein, especially during serious infections, is not trivial. It is estimated that in moderate infections, the average daily protein loss is 0.6 g/kg/day, the

### Box 5-2 Effects of Infection on Host's Nutritional Status

1. Decreased intake (anorexia)
2. Protein catabolism and negative nitrogen balance
3. Depletion of carbohydrate stores
4. Altered fat metabolism
5. Pseudodiabetic state—hyperinsulinemia, increased insulin resistance, raised glucagons and glucocorticoid levels
6. Increased basal metabolic rate
7. Increased gluconeogenesis
8. Decreased absorption (symptomatic and asymptomatic gastrointestinal infections)
9. Micronutrient sequestration (Fe, Zn)
10. Nutrient wasting (Zn loss in diarrhea, protein and vitamin A loss in shigellosis)

recommended daily intake for adults. Losses in dysentery are slightly higher (0.9 g/kg/day), and in severe infections, including typhoid fever, daily protein loss approached 1.2 g/kg/day.<sup>115</sup> Although proteolysis may serve in the short-term as a source of amino acids for new protein synthesis, the continuous consumption of proteins must, at a given point, have adverse consequences for the host. Changes are clinically manifest as wasting, and wasting of more than 55% of the lean body mass is incompatible with life, regardless of the cause.<sup>116,117</sup>

### Alterations in Carbohydrate Metabolism

The inflammatory response induces a metabolic state characterized by increased gluconeogenesis secondary to cytokine upregulation of the rate-limiting enzyme phosphoenolpyruvate carboxykinase<sup>118</sup> even when exogenous carbohydrate intake is adequate. Serum levels of insulin, glucagon, and corticosteroids are all increased. The metabolic result is a syndrome of hyperinsulinemia, insulin resistance,<sup>119</sup> depressed glycogenesis and fat catabolism,<sup>120</sup> and enhanced peripheral glucose uptake and utilization. Precursor amino acids are deaminated, the nitrogen is converted to urea (which is excreted in urine), and the glucose derived from the carbon backbone is oxidized for energy.

### Alterations in Mineral Metabolism

The divalent cations iron and zinc are highly protein bound. During the inflammatory response, significant shifts in the distribution of these minerals occur in physiologic compartments. Iron and zinc are sequestered by the cytokine-induced synthesis of their binding proteins, ferritin and metallothionein. Sequestration of zinc and iron is in direct proportion to the severity of the infection, and zinc levels can fall to half normal levels and iron can become almost undetectable.<sup>121</sup>

## GASTROINTESTINAL INFECTIONS

Gastrointestinal infections have a particularly important role in inducing a compromise in host nutritional status. Malabsorption in gastrointestinal illness may result from the epithelial destruction by the pathogen or by the immune response to the pathogen. Even common diarrheal illnesses can have a profound impact on nutrient absorption. In symptomatic rotavirus infection, the most common cause of acute severe diarrheal illness worldwide, there is a 42% decrease in the absorption of nitrogen and fat, a 48% decrement in the absorption of carbohydrates, and a 55% decrease in the total energy absorption.<sup>122</sup> These indices for malabsorption are slightly more severe in both ETEC infections and shigellosis.<sup>25,122</sup> In shigellosis,<sup>123</sup> protein loss is sizable and important, and vitamin A is wasted.<sup>27</sup> Giardiasis and ascariasis lead to the malabsorption of vitamin A.<sup>24</sup> Large losses of zinc also occur in diarrhea.<sup>124</sup>

## EFFECTS OF MALNUTRITION ON HOST IMMUNE FUNCTION

### Innate Immunity: Physical Barriers

The primary physical barrier to infection, the integument, is affected by a wide variety of nutrient deficiencies. Skin lesions

are one of the cardinal signs of kwashiorkor. Protein energy malnutrition or even more milder forms of nutritional depletion can be correlated with decreased gastrointestinal mucosal integrity as measured by the lactulose:mannitol ratio.<sup>125</sup> Also, vitamin A deficiency has been found to have a similar effect on gut integrity by the same test.<sup>126</sup> Striking histological changes are noted in the epithelia of vitamin A-deprived animals characterized as metaplastic hyperkeratosis that are rapidly reversible upon vitamin A repletion.<sup>127,128</sup> Although severe zinc deficiency results in characteristic skin lesions,<sup>129</sup> mild to moderate zinc deficiencies also compromise the integrity of the gastrointestinal and respiratory epithelia.<sup>130,131</sup> Indeed, specific nutrient deficiencies are often manifest by epithelial lesions: Dermatitis and mucosal atrophy are noted in pellagra; dermatosis and dermatitis, cheilosis, and angular stomatitis are manifest in pyridoxine deficiency; and subcutaneous atrophy and tissue fragility are seen in scurvy. The nonessential amino acid glutamine also appears to have a role in the maintenance of intestinal epithelial integrity.<sup>32</sup>

### Innate Immunity: Phagocytic Cells

Neutrophils and macrophages are the first-line generalized response to invading organisms. There is dispute about diminished neutrophil chemotaxis and adhesion in PEM,<sup>132–134</sup> but there does appear to be a diminished bactericidal killing despite a normal generation of oxidative metabolites.<sup>133,135</sup> Additionally, serum opsinin activity is notably depressed in patients with PEM,<sup>136</sup> and this is likely to further diminish the microbicidal functions of neutrophils. Zinc facilitates neutrophil activity directly<sup>137–139</sup> and indirectly through the stimulation of opsonic activity.<sup>139</sup> Iron deficiency causes a decrease in neutrophil chemotactic activity and bactericidal capacity; the latter is thought to be due in part to diminished myeloperoxidase (an iron-containing enzyme) and in part to hexose monophosphate shunt activities in phagocytic cells.<sup>140</sup> However, there is a balance as high-dose iron infusions depress, at least temporarily, intracellular killing in dialysis patients.<sup>141</sup>

Macrophages play a dual role in host defense. Once activated by lymphokine signals, macrophages may act directly as a microbicidal effector against intracellular pathogens, including viruses, certain bacteria and fungi, as well as protozoa. In addition to these direct functions, macrophages are the key antigen presenting cells for T lymphocyte proliferative responses and cytokine production. Although it is clear that malnourished hosts are at an increased risk of infection due to intracellular pathogens, it is difficult to separate the direct effects on macrophage phagocytosis and microbial function from the indirect effects due to impaired antigen presentation and reduced T cell responses that are necessary to stimulate normal macrophage activation. Despite this, it has been noted in murine models that macrophages from protein-restricted animals are abnormally sensitive to apoptotic stimuli.<sup>142</sup> In children with PEM, a markedly delayed and diminished macrophage migration was noted using the Rebuck window technique.<sup>134</sup> In addition, in murine models diminished adhesion, activation, and delayed phagocytosis were demonstrated.<sup>143,144</sup>

Macrophages appear to have decreased antigen presenting capacity and possibly a diminished capacity for normal coordinated signaling with T cells. A study of activated macrophages from protein-restricted and -sufficient diets revealed that the

phagocytosis of *Candida albicans* and the generation of superoxide in response to phorbol myristate acetate were significantly diminished in the low-protein diet group using cells from both unprimed and BCG-primed animals, suggesting direct effects of malnutrition on the macrophage.<sup>145</sup> The study also evaluated deficits in antigen presentation by using D.10 cells, a standard Th clone derived from AKR mice and incubated with low or normal protein diet macrophages and the soluble antigen conalbumin. This assay measures the resulting incorporation of <sup>3</sup>H-thymidine into DNA if antigen presentation is normal. The production of cytokines by the responding T cells, particularly interferon- $\gamma$  (IFN- $\gamma$ ), then activates the macrophages for intracellular killing and the production of counter-regulatory substances, nitric oxide and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), which dampen the lymphocyte response. No differences in thymidine incorporation were observed using resident or BCG-activated cells, and the expression of Ia, the class II major histocompatibility complex antigen, was only slightly reduced in the low-protein group. The mixed lymphocyte reaction, used to assess the response to particulate allogeneic antigens, was also preserved in the low-protein diet group. However, a marked decrease in macrophage production of NO and PGE<sub>2</sub> was observed, which would be expected to enhance lymphocyte proliferation by diminishing the negative regulatory signals for these cells. Whether this macrophage defect resulted from decreased secretion of IFN- $\gamma$  by the responding T cells or decreased response of macrophages to IFN- $\gamma$  signaling is not clear.

There is evidence for both altered intracellular signaling following endotoxin stimulation<sup>146</sup> and altered cytokine responses under multiple experimental conditions in PEM. In one study of cytokine responses, the plasma levels of IL-6 and the p55 and p75 soluble receptors for TNF- $\alpha$  were elevated in children with PEM, especially in the presence of severe PEM with edema, independent of the presence of clinical infection.<sup>147</sup> In contrast, a study on Turkish children without apparent infection found decreased IL-1 levels compared with control subjects, but IL-1 increased during infection in a manner similar to that of the controls.<sup>148</sup> These findings are consistent with prior data in humans showing that in vitro production of IL-1 by lipopolysaccharide (LPS)-stimulated peripheral blood monocytes was depressed in severe PEM compared with controls.<sup>149,150</sup>

In humans with acrodermatitis enteropathica, the monocyte chemotactic response is suppressed and can be normalized by the addition of zinc in vitro.<sup>131,151</sup> In a murine model, zinc deficiency was found to adversely affect monocyte uptake and killing of *Trypanosoma cruzi* in a dose-dependent manner,<sup>152</sup> and zinc-deficient mice exhibited macrophage-mediated depression of T cell proliferation that could be corrected in vitro by the addition of zinc.<sup>153</sup> The extent to which these events occur in common infections in humans is unclear.

## Adaptive Immunity

### Protein Energy Malnutrition

Protein energy malnutrition profoundly affects the adaptive immune response through diverse mechanisms. Abundant data show that T cells are especially affected, particularly T helper cells, and these deficits are largely mediated through

defects in the T cell maturation process. However, important alterations in B cell function, immunoglobulins, and complement are also present. Understanding the effects of PEM is further complicated because study populations almost certainly suffered micronutrient deficiencies at a time when they were not readily identified, and the accurate attribution of immune deficits to one type of undernutrition is not possible.

During the past 150 years, a number of studies have documented a major impact of malnutrition on lymphocytes, long before the concepts of T and B lymphocytes were proposed and methods were developed to identify them. For example, anatomical and histopathologic examination of the thymus, spleen, and lymph nodes in people dying of malnutrition has revealed involution of the thymus and depletion of populations of lymphocytes from the peripheral lymphoid organs, now known to be predominantly populated with T lymphocytes. However, the number of circulating lymphocytes was only mildly diminished or often normal. Later, when it became possible to distinguish T cells from B cells, it was noted that there was a decrease in the number of mature functioning T lymphocytes, an unchanged number of B cells, and an increase in the number of cells that expressed neither T or B cell markers (null cells).<sup>154,155</sup> However, the degree of malnutrition as assessed by anthropometry did not correlate to the percentage of mature and immature T lymphocytes in circulation, and there was considerable individual variation.<sup>155</sup> Studies using monoclonal antibodies to identify lymphocyte subpopulations in Bolivian infants with severe PEM and thymic involution (greater than 90% decrease in thymic size by ultrasonography) have shown a statistically significant decrease in the percentage of mature CD4+ cells, an increase in the percentage of CD1a+ precursor cells and CD8+ Tc and Ts cells, and no change in the percentage of CD21+ B cells in the malnourished compared to normally nourished controls.<sup>156</sup> All these results support a significant deficit affecting the T cell maturation process in individuals with PEM.

The mechanisms that mediate the deficit in T cell maturation are not clear. T cells are so named because stimuli for the maturation of pluripotential lymphocyte precursors along the T lineage are derived from the thymus gland, whereas the maturation signals for B cells are in the bone marrow. The thymus is a compound organ with both epithelial and stromal elements surrounding islands of developing lymphocytes. The thymic epithelium produces a variety of zinc-binding peptides, such as thymosin and thymulin, which have been shown to drive maturation of T lymphocytes in vitro. Lymphocytes from Bolivian children with PEM that are incubated with thymulin in vitro showed an increased percentage of CD4+ cells at the expense of CD1a+ precursors, with no observed change in the percentage of CD21+ B lymphocytes.<sup>156</sup> Studies of lymphocytes of Guatemalan children undergoing incubation with thymosin 5 show consistent findings.<sup>157</sup> These findings taken together strongly suggest that the thymic microenvironment is altered in vivo, and that this alteration causes severe abnormalities in T cell number and function, especially in the maturation of CD4+ cell lines.

Th lymphocytes also differentiate along two functionally polarized lines, Th1 and Th2, under a diverse range of influences, including the cytokine milieu, the nature of the protein ligand, cortisol, norepinephrine, and microbial burden.<sup>158</sup> Th0 cells are stimulated to differentiate into Th1 cells under

the influence of IL-12 and produce IL-2, IFN- $\gamma$ , and TNF- $\beta$ . IFN- $\gamma$  stimulates antigen presentation through the upregulation of both major histocompatibility class I and class II molecules on a wide variety of cell types. IL-12, among other things, blocks the differentiation of Th0 cells into Th2 cells. The response mediated by Th1 cells, a type 1 response, is characterized by a strong cell-mediated immune response and phagocytic activity and a relatively weaker humoral response. On the other hand, Th2 cells differentiate under the influence of IL-4 and secrete IL-4, IL-5, IL-10, and IL-13. IL-4, IL-10, and IL-13 stimulate B cell development, antibody production, and immunoglobulin class switching. Furthermore, IL-4 inhibits the differentiation of T0 cells into T1 cells. The response mediated by Th2 cells, type 2 immunity, is characterized by a strong humoral response. The tendency of one response (type 1 or type 2) to limit the other results in polarization of the immune response.

The extent to which PEM alters Th polarization is not well studied. However, in a study of Turkish children with PEM, IL-6 was noted to be significantly elevated, whereas TNF- $\beta$  levels were not different from those of the control group, leading the authors to conclude that PEM favored a type 2 response.<sup>159</sup> Findings from a murine model support this hypothesis.<sup>160</sup> Delayed-type hypersensitivity skin response is a measure of cell-mediated immunity, which is dependent on Th1 cell activity. Defects in skin test reactivity to recall antigens such as tuberculin and *C. albicans* are prevalent in individuals with PEM. This is not a new observation: During the mid-1960s, prior to the discovery of the T and B lymphocyte lineages and T cell subpopulations, diminished prevalence and size of the tuberculin reaction were observed in African children with PEM compared to better nourished children from the same environment, and the tuberculin response to BCG vaccine was blunted as well.<sup>161,162</sup> Because tuberculosis has long been associated with malnutrition, the adverse effects of PEM on cell-mediated immune responses, the principal host defense against *Mycobacterium tuberculosis*, may be an important determinant of outcome. In fact, one study has shown that peripheral blood monocytes from malnourished tuberculosis patients produced no more IFN- $\gamma$  when stimulated in vitro than controls, suggesting that defective IFN- $\gamma$  responses by Th1 cells in malnutrition contribute to the susceptibility of malnourished hosts to tuberculosis.<sup>163</sup>

The percentage of B lymphocytes in the circulation remains in the normal range in PEM patients, consistent with the preservation of the cellularity of B lymphocyte-rich regions of the peripheral lymphoid organs. These cells are functional, and PEM patients usually have elevated serum levels of IgG, IgM, and IgA, especially in the presence of infections. However, normal immunoglobulin levels do not mean that antibody production is normal as well. More important than the total quantity of immunoglobulin are the amount and quality of specific antibody present and the ability of B cells to produce antibodies in response to new antigens.

There are limited data on the production of specific antibodies in PEM patients, mostly from studies using the response to vaccines as the experimental model. The majority of these have involved the use of the T lymphocyte-dependent protein tetanus toxoid and typhoid vaccine, which contains T-dependent protein antigens, the flagellar H antigens of *Salmonella typhi*, and T-independent somatic O antigens.

Because of the large body of evidence showing that Th cells are diminished in PEM and the additional information that the immune response seems to be type 2 primed in PEM, the expectation is that PEM will inhibit the response to tetanus toxoid and flagellar H antigens and not significantly effect the response to the O polysaccharide. However, PEM patients appear to respond well to tetanus<sup>164</sup> and to flagellar antigens but not to polysaccharide antigens,<sup>165,166</sup> suggesting that at least some T-dependent responses occur normally but that there is a defect in the response to carbohydrate antigens.<sup>167</sup> Other vaccines have been tested with variable results, sometimes<sup>168–170</sup> but not always<sup>171,172</sup> showing a compromised antibody response. In a study of household contacts of adult cholera patients in Bangladesh, children 1 to 8 years of age were given two oral doses of cholera toxin B subunit, the non-toxic portion of cholera toxin, or placebo within 24 hours of hospitalization of the index adult patient. Although one-third of the children became infected with cholera (half symptomatic with diarrhea), malnourished children (weight for age <70% of the standard) did not differ from well-nourished children in the concentrations of salivary total IgA, initial serum antitoxin, or vibriocidal antibodies or in their serologic response to colonization, disease, or the toxin B subunit.<sup>173</sup>

Although total IgG levels are normal or elevated in PEM, antipolysaccharide antibodies are commonly of the IgG-2 or IgG-4 subclass. Thus, in response to respiratory infections with encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenza* type b (Hib), IgG-2 and IgG-4 antibodies are either made locally in the lung or are transported into pulmonary secretions.<sup>174</sup> It is possible that the susceptibility of children with PEM to bacterial encapsulated respiratory pathogens is due to defects in the production of optimal IgG subclass antibodies, but the question has not been fully addressed. On the other hand, trials of the Hib conjugate vaccine in the Gambia effectively eliminated Hib disease, including in children with mild to moderate malnutrition.<sup>175</sup>

Can we make sense of the different vaccine challenges used to elicit antibody responses and the variable results obtained? Unfortunately, clarity and conclusiveness remain illusive. In part, this is because vaccine studies in PEM patients have generally tested the antibody response at the end of 4 weeks or longer following booster doses, and the early response, detectable within days of immunization, has not been examined. However, in real infections (in contrast to immunization), the kinetics of the immune response is crucial to adequate host defenses. Therefore, normal percent seroconversion or even levels of antibody weeks after the original vaccine dose, or even later following a booster dose, do not predict whether the early responses were also normal. In one study of the response to measles vaccine, a delay in specific immune response, measured on days 21 and 42 postimmunization, was noted in children with PEM.<sup>176</sup> The late response may represent a catch-up synthesis of antibody in PEM, sufficient to induce protection against a subsequent infection, but if the early response is delayed or of diminished magnitude in response to the actual infectious agent, then it may not contribute to host defense during infection and may lead to an adverse outcome.

The secretory immune system has also been assessed in individuals with PEM and consistently found to be deficient.<sup>177</sup> For example, a study of the response to measles and oral polio

vaccines revealed diminished sIgA levels in saliva and specific IgA antibody responses following immunization of these patients.<sup>178</sup>

When measured in PEM patients, all components of serum complement except C4 have been observed to be significantly reduced, especially C3 and factor B.<sup>179</sup> As a result, both the classical and the alternate pathway are affected, although in vitro assays of complement-dependent hemolysis indicate that the compromise to the antibody-independent and early acting alternate pathway is more severe.<sup>180–182</sup> The high degree of activation of complement and elevated level of circulating complement–antibody complexes and the paradoxical decline in C3 levels in children with PEM and a concurrent infection<sup>178</sup> all suggest that complement activity is at least in part explained by a consumptive process, probably amplified by deficits in synthesis of complement components.<sup>180</sup>

### Vitamin A

Despite the large body of data demonstrating a clear benefit of vitamin A on child survival, there is a paucity of data on the mechanisms by which vitamin A deficiency alters immune function. Vitamin A-deficient children have a decreased CD4/CD8 and cell ratio that can be normalized with vitamin A.<sup>183</sup> However, the strongest effects of vitamin A deficiency on adaptive immunity are regulated through the induction of a cytokine profile that favors a type 1 over a type 2 response<sup>184–186</sup> that can inhibit antibody responses, especially to polysaccharide antigens.<sup>187</sup> In animal models, high levels of vitamin A augment the type 2 response, even when stimulated by a type 1 antigen such as influenza A.<sup>188</sup> Concern about possible adverse effects of vitamin A on immune responses arose when a defect was noted in the seroconversion rate of 6-month-old children given vitamin A at the time of measles immunization.<sup>183</sup> Because a practical way to give vitamin A was through the delivery structure provided by immunization, this early finding raised concern; however, a group of subsequent studies that measured the immunologic response to measles vaccine at 9 months of age,<sup>189</sup> oral polio vaccine,<sup>190</sup> and DPT<sup>191</sup> vaccine failed to show any adverse event of concurrent vitamin A administration on the antibody response to any of the antigens in these vaccines.

### Zinc

Zinc deficiency has diverse effects on adaptive immunity. The most profound deficits induced by zinc deficiency involve T cell-mediated immune responses, especially type 1 responses. Zinc-deficient mice have reduced numbers of T cells, reduced proliferative responses to both mitogens and specific antigens, decreased IL-2 production, and decreased antibody levels to a T-dependent antigen but not a T-independent antigen.<sup>192</sup> All these changes were reversible with zinc supplementation.<sup>151,192,193</sup> These results are consistent with findings in children with PEM in whom nutritional rehabilitation failed to correct thymic gland involution (measured by chest radiographs) until 2 mg/kg/day of zinc was added to their diet. In malnourished children with diminished DTH skin test results, zinc has been demonstrated to augment DTH responsiveness.<sup>194,195</sup> Lymphocyte proliferative responses were greater in children with shigellosis receiving adjunctive zinc therapy than in controls.<sup>196</sup>

Zinc deficiency inhibits thymulin activity and thereby limits both intrathymic and extrathymic T cell differentiation.<sup>197</sup> Zinc deficiency also limits peripheral T cell activation and division through diminished IL-2 production,<sup>198</sup> and by decreasing the activity of NF- $\kappa$ B<sup>199</sup> and downregulating the interaction between IL-2 and IL-2 receptors, the responsiveness of T cells to IL-2 is reduced.<sup>200</sup> In addition to decreased IL-2, production of IFN- $\gamma$  and TNF- $\alpha$ , cytokines critical for a normal type 1 response, is compromised,<sup>198</sup> whereas the production of the type 2 cytokines IL-4, IL-5, IL-6, and IL-10 remains intact,<sup>198,201</sup> leading to a distinct polarization in T cell response.

Animal studies also support some degree of impairment of B cells due to zinc deficiency, although the effects seem less than those seen in T cells. Pre-B cells and immature B cells, but not mature B cells, are reduced in number during zinc deficiency secondary to glucocorticoid-mediated apoptosis.<sup>202</sup> The patency of the humoral response in zinc deficiency appears to be highly dependent on the antigen. In a murine model, induced zinc deficiency had no detectable effect on the IgM response following immunization with a pneumococcal polysaccharide vaccine,<sup>203</sup> whereas in the same murine model with a T cell-dependent pneumococcal surface protein A vaccine, the IgG response was significantly decreased at both 14 and 28 days. In animals that underwent subsequent pneumococcal challenge, zinc-deficient animals exhibited heavier colonization and were more likely to become septicemic and die than controls.<sup>204</sup> Similar results have been obtained in humans. Two studies of the immunologic response to the oral killed whole cell plus cholera toxin B subunit cholera vaccine demonstrated an increased serum vibriocidal response and a decreased cholera toxin response in zinc-supplemented individuals.<sup>205–207</sup> In one of these studies, fecal anticholera toxin was increased.<sup>205</sup> Vibriocidal antibodies are directed against an LPS antigen and should induce a T-independent response, whereas cholera toxin is a protein and should induce a T-dependent humoral response.

### CLINICAL POINTERS

Generally, professionals in public health have accepted the large body of evidence linking malnutrition and infection and act to implement appropriate interventions. Clinicians, however, often fail to recognize malnutrition, particularly milder forms, or to institute and monitor adequate nutritional therapy in patients with concurrent infections. Even mild to moderate malnutrition can be an important determinant in the outcome of an infectious disease. Patient management will be optimized only when clinicians incorporate appropriate nutritional therapy and counseling into clinical practice. Conversely, cytokine-induced losses of muscle mass and body nutrients occur during infections, even in previously well-nourished individuals who receive prompt and effective therapy. These losses can be fully reversed by convalescent feedings and micronutrient supplementation. Despite adequate replacement diets, it generally takes two or three times as long to replete an individual than it took to deplete him or her,<sup>5</sup> and the period of nutritional convalescence will depend on both the chronicity and the severity of the infection. In general, it is recommended that children should receive 30% more calories and 100% more protein to allow for catch-up growth

during convalescence. Plentiful early and frequent feedings are especially important for infants and children in order to reinitiate an anabolic state and prevent a cycle of intensified progressive malnutrition often associated with frequent or recurring infections.

Individuals with severe malnourishment (WHZ  $<-3$ ) greatly benefit from management accorded by structured protocols. Implementation of standardized management protocols in Bangladesh and Brazil has greatly improved outcome measures and decreased case fatality rate following protocol institution.<sup>208,209</sup> Because malnourished patients suffer atrophy of the intestinal mucosa, along with diminished production of hydrochloric acid and digestive enzymes, refeeding may be clinically difficult. Adequate amounts of potassium, phosphate, magnesium, zinc, and other vitamins must be replaced judiciously and energy requirements and intake measured and adjusted carefully during therapy.<sup>210,211</sup> Weight gain must be accurately measured, recorded, and diligently monitored to assess the adequacy of response to therapy. Infections are common and need to be identified and treated early.

Because important forms of malnutrition cause lymphoid atrophy, quick estimation of tonsillar size in a malnourished child provides instantaneous clinical information about the potential functional competence of the immune system. Tonsils virtually disappear during severe malnutrition.

Because vitamin A deficiency is widespread in developing countries, careful eye examinations are a mandatory part of patient evaluation. Both corneal xerophthalmia (xerosis, ulceration, and necrosis) and mild xerophthalmia are authentic clinical indicators that the patient faces an increased risk of morbidity and mortality as well as blindness. Prompt treatment with vitamin A is essential. Because vitamin A deficiency generally occurs in clusters, the presence of xerophthalmia in an index patient should raise the suspicion that family members and possibly the community as a whole share the deficiency. Vitamin A prophylaxis and dietary counseling should extend beyond the index patient. Because vitamin A deficiency increases mortality and the severity of infections before evidence of xerophthalmia, children in most developing countries should receive vitamin A at regular intervals. Although beyond the scope of this chapter, biofortification of the food supply through improvement of the quality of foods rather than supplementation of individuals with vitamin A and other micronutrients is critical if we are to address the nutritional needs of the 9 billion people who will populate Earth by 2050.

Although adequate iron intake is necessary to prevent iron deficiency anemia, caution needs to be exercised in regard to infectious diseases. It is recommended that iron supplements be withheld until initial management of severe malnutrition, which may be accompanied by serious infections. Children who present with infectious diseases and anemia should not be started on iron supplements until the infection is treated. The possible increase in some infections, such as malaria and diarrhea, with routine iron supplementation needs to be considered along with the possible benefits in deciding if this should be done in various settings. High-dose vitamin A administration is a mandatory part of treatment for all children with measles.

Preschool children with diarrhea should receive zinc (20 mg/day for 10–14 days; half this dose for children  $<6$  months old) along with oral rehydration therapy, including increased fluids and continued feeding.

## Host Genetics and Susceptibility to Infection

ROBERT JOHN WILKINSON  
MICHAEL LEVIN  
GEOFFREY PASVOL

The dawn of the scientific age of medicine in the late 19th century was characterized by the discovery of many of the microorganisms responsible for conditions such as tuberculosis and malaria. At the beginning of the 21st century, the availability of representative whole genome sequences of more than 50 common pathogens heralds a new age of molecular microbiology and parasitology. As a consequence, our consideration of infectious disease tends to be “organism based,” with great emphasis on virulence determinants responsible for pathogenicity. In the first half of the 20th century, improvements in living conditions resulted in reduced incidences of many of these infectious diseases, thus emphasizing the importance of the environment as a major influence on the occurrence of infection. Only the rash are trumpeting the death knoll of infectious diseases, however: More people died per day of infection in 2000 than in 1900.

Toward the middle of the 20th century, the concept that the genetic makeup of the host may influence the outcome of infection became apparent, and in this respect malaria served as a prototype. All but a few infectious diseases are characterized clinically by variation in both disease pattern and severity, even in epidemic circumstances, indicating that host response has an important influence on the outcome of disease. A classic study highlighted the importance of host genetic makeup in our susceptibility to infection.<sup>1</sup> The cause-specific risk of dying in adopted children was compared, depending on whether their biologic (genetically related) or adoptive (environmentally related) parent died prematurely before the age of 50 years. The results were striking. The death of a biologic parent resulted in an increased relative risk of dying in the adoptee of 5.8 for infectious diseases, more than for cardiovascular disease (4.5) and much more than for cancers (1.2). The advent of molecular biology embracing the “new genetics” and major advances in our understanding of the structure and function of the immune system have provided tools for the more precise dissection of the role of genetic factors that influence the outcome of infection. One hypothesis is that infection may have been one of the major architects of genes coding for the immune response through generations of natural selection.

### GENERAL CONCEPTS

It is rare for a simple Mendelian pattern of inheritance to be apparent when considering the genetic influence on infectious disease. An exception is malaria, in which the parasite's intraerythrocytic lifestyle is influenced by a variety of both red blood cell membrane and hemoglobin variants whose inheritance is relatively simple. As a consequence, malaria has been a very fruitful model for studies of host susceptibility to infectious disease. In most infectious diseases, however, the pattern of inheritance influencing susceptibility is not as clear and is assumed to be complex. Furthermore, the effects of host genes are modified both by environmental factors and by variation in the infecting organism. There are a number of genetic features and general concepts that apply to any consideration of the genetic basis of resistance (or susceptibility) to infection:

1. The traits involved are complex. It is often impossible to find a genetic marker that shows complete cosegregation with a complex trait. The reasons are well stated by Lander and Schork<sup>2</sup>:
  - a. Incomplete penetrance and phenocopy: A mutant gene product may have a major influence, but its effect may be compensated for by other mechanisms. Alternatively, a given mutant may give rise to a phenotype that can also arise in the absence of that mutant (phenocopy).
  - b. Genetic heterogeneity: Mutations in any one of several genes (e.g., in a biochemical pathway) may give rise to the same phenotype. A good example is given by deficiencies of the interacting complement factors C3, I, or H, which may predispose to infection with encapsulated bacteria.
  - c. Polygenic inheritance: Some traits may require the simultaneous presence of variation in multiple genes. This is likely to be the case for most infectious diseases. As more genes influencing susceptibility are discovered, one of the major challenges will be to rank their order of importance.
  - d. A high frequency of a disease-associated allele makes the attribution of risk and linkage analysis more difficult. For example, a number of studies have examined the relationship between HLA-DR2 and tuberculosis. The universal problem has been the high general frequency of this allele in the populations under study. Since the HLA-DR2 allele is present in approximately 40% of people in southern India, and in 60% of patients with tuberculosis,<sup>3</sup> a major effect may therefore be missed as a consequence of the difficulty in attributing risk.
2. The protection conferred may only be relative. The possession of red blood cells negative for the Duffy antigen, and the resistance it provides against vivax malaria, is one of the few examples in humans of absolute genetic protection against an infection.<sup>4</sup> In most other circumstances protection is relative. Although people with the sickle cell trait have up to 90% protection against malaria, they can undoubtedly become infected and die of falciparum malaria. Glucose-6-phosphate dehydrogenase (G6PD) deficiency may provide between 50% and 60% protection,

whereas people with  $\alpha$ -thalassemia may have as small a margin of protection as 5%.<sup>5</sup> Thus, “protection” is rarely absolute and should only be discussed at the population, rather than the individual, level.

3. The heterozygous rather than homozygous state may confer protection. This is the classic concept of “hybrid vigor.” A “double dose” of a protective gene may not be additive in the protection it provides and can even be deleterious. The best example of this phenomenon is in sickle cell carriers (AS), who have a reduced risk of dying of falciparum malaria, whereas the consequences of malaria in a patient with sickle cell disease (SS) may be disastrous.
4. Protection may be highly specific. Protection offered by a genetic trait may be specific on a number of counts. First, protection may exist not only for a disease, for example, malaria, but also for malaria caused by a specific species of parasite. Thus, sickle cell trait carriers are protected against falciparum malaria but not, as far as is known, against the other three *Plasmodium* species in man (i.e., *P. vivax*, *P. ovale*, and *P. malariae*). Second, protection may be specific for a particular clinical or pathologic form of the disease. An example of this is the class I major histocompatibility complex (MHC) antigen B53, which is associated with protection against both cerebral malaria and severe malarial anemia, whereas the class II haplotype, DRB1\*1302, is only protective against anemia.<sup>6</sup> Alternatively, protection may apply to only a particular age group; for example, sickle cell trait carriers living in an endemic area for malaria are mainly protected between the ages of approximately 6 months and 5 years, at the time when passively acquired, antibody-mediated protection from the mother has waned and the individual has not as yet developed actively acquired immunity. Sickle cell trait may hasten the development of acquired immunity.
5. Genetic protection afforded against one disease may result in susceptibility to another. The existence of polymorphism implies that where an apparently deleterious allele persists in a state of balanced polymorphism within a population, there should be selective pressure in favor of that persistence, perhaps mediated by protection against a second disease. For example, homozygosity for a rare polymorphism at position -308 in the tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) promoter region confers a 7.7 times increased risk of dying of cerebral malaria. The persistence of the rare allele in the population at a frequency of 16% implies that it confers protection against another, as yet unidentified infection or disease.<sup>7</sup>

## ELEMENTS OF THE IMMUNE SYSTEM

### Nonimmune Mechanisms

Molecular genetics has made extraordinary advances in the understanding of the genetic basis and potential treatment of a large number of inherited conditions, some of whose frequency in the tropics is unknown. One such condition is cystic fibrosis caused by a mutation in the chloride transporter cystic fibrosis

transmembrane conductance regulator gene (*CFTR*) on chromosome 7.<sup>8</sup> The mutant *CFTR* with phenylalanine at position 508 resists the entry of both *Pseudomonas* and *Salmonella typhi* into epithelial cells.<sup>9,10</sup> Clinically, this gives rise to differing consequences: *Pseudomonas* is not internalized and thereby multiplies to high numbers in abnormally viscid secretions that cannot be cleared. In contrast, there is reason to suspect heterozygosity for the *CFTR* mutation may confer resistance to typhoid. Another example is the primary ciliary dyskinesias (PCD) including Kartagener's syndrome, in which an abnormality of ciliary action leads to a defect in epithelial clearance with consequent chronic lung infection, which may lead to bronchiectasis, necessitating lung transplantation. Progress in defining the genetic cause of these heterogeneous defects has been made as mutations in intermediate-chain dynein (DNAI1; IC78) have been described in some PCD patients.<sup>11</sup>

### Innate Immunity

Excepting the unique example of innate protection by red blood cell variants in malaria, the innate system consists of three major elements: serum factors, phagocytic cells, and natural killer (NK) cells. Complement is a proteolytic cascade system consisting of at least 24 serum proteins and 11 membrane-bound proteins. The majority of the complement components are present in the plasma as inactive precursors. Triggering of the complement cascade results in opsonization or lysis of infecting organisms. Chemotactic molecules such as C5a are generated and immune complexes are solubilized. Activation can occur via the binding of antigen-bound IgG or IgM to the first complement C1 (classical pathway). The alternative, antibody-independent pathway involves the activation of C4 and C2 by a plasma serine protease in complex with mannose-binding lectin (MBL), which in turn is bound to suitable carbohydrate ligands present on the surface of bacteria or viruses. The genes for many of the complement components have been identified and the effect of deficiency is listed in Table 6-1. Another line of defense includes lactoferrin, lysozyme, as well as the collectins and defensins. Activation of these molecules can lead directly to lysis of pathogens or to destruction through opsonization or the recruitment of inflammatory cells. The main function of phagocytes is to surround, ingest, and destroy organisms by the process of phagocytosis. Phagocytes, in the form of dendritic cells, also process and present antigens from microorganisms to lymphocytes. A third function of phagocytes is the production of soluble molecules, cytokines and chemokines, which orchestrate the inflammatory process. NK cells belong to a different lineage and can destroy virally infected, embryonic, or tumor cells. Major interest in how phagocytes recognize pathogens has been stimulated by the discovery of the Toll-like receptors (TLRs), whose differential engagement by pathogens can induce overlapping yet distinct patterns of gene expression that contribute to an inflammatory response.<sup>12</sup> In addition, antigen-presenting cells (APCs) employ other pattern recognition receptors, including complement receptor 3 (CR3), scavenger receptors, the mannose receptor, and various other C type lectins such as DC-SIGN.<sup>13</sup> These molecules appear conserved through evolution but the possibility that minor variation within these receptors contributes to susceptibility to infection has attracted attention.<sup>14,15</sup>

**Table 6-1** *Inherited Conditions Predisposing to Infectious Diseases and Their Genetic Basis*

Syndrome	Clinical Features	Defect	Genetic Basis	References
Chronic granulomatous disease	Presents in the first years of life with severe recurrent bacterial and fungal infections	Failure of intracellular O <sub>2</sub> <sup>-</sup> production	X-linked or autosomal recessive with defects in NADPH oxidase subunits	123–125
X-linked immunodeficiency syndromes	Chronic sinopulmonary infection, chronic diarrhea, and hepatitis			
X-linked agammaglobulinemia	As above	Agammaglobulinemia	Mostly due to mutation in Bruton's tyrosine kinase gene	126
Common variable immunodeficiency	As above		Probable multiple; occasional adult-onset cases homozygous for mutations in ICOS	127, 128
Hyper-IgM syndrome	As above	Lack of IgG, IgA, and IgE	Mutation in CD154 (CD40 ligand)	129
Wiskott–Aldrich syndrome	Eczema, thrombocytopenia, recurrent infections, autoimmune disorders, IgA nephropathy	Mutations in the Wiskott–Aldrich protein, a regulator of platelet and lymphocyte function		130–132
Severe combined immunodeficiency	Severe and persistent infection from early life	Decreased T cells and abnormal thymic differentiation	Mutations in IL-2R $\gamma$ , Jak3, IL-7R $\alpha$ , RAG1, RAG2, Artemis, CD3 $\delta$ , adenosine deaminase, and CD45	133
C1	SLE-like illness and increased susceptibility to infection	Lack of expression of C1q, C1r, or C1s		134, 135
C3	Increased susceptibility to encapsulated bacteria			136
Factors I and H	As above	Both are cofactors for C3; deficiency therefore gives rise to the same susceptibility		137
C4	Bacterial meningitis	Failure of C4B expression		138
Properdin	Meningococcal disease	X-linked		139
C5–C9	Meningococcal disease			140
Mannose-binding lectins (MBLs)	Unusual and recurrent infection; carriage of hepatitis B	Mutation in codon 52 or 54 of exon 1 of the MBL gene		89, 91, 141

## Acquired Immunity

The predominant effector and regulatory cell in the acquired response is the lymphocyte. B lymphocytes produce antibody that attaches to foreign organisms, facilitating their destruction by a number of mechanisms. Their response is regulated by regulatory T cells, mainly CD4+. In addition, cytotoxic T cells, mainly CD8+, can be effector cells that kill infected cells. All T lymphocytes recognize foreign antigen presented by an APC via major histocompatibility complex (MHC) class I and class II molecules. Classical antigen-presentation studies showed that MHC class I molecules present peptides derived from proteins synthesized within the cell, whereas MHC class II molecules present exogenous proteins captured from the environment. Evidence indicates, however, that dendritic cells have a specialized capacity to process exogenous antigens into the MHC class I pathway. This function, known as cross-presentation, provides the immune system with additional flexibility to generate immunity to viruses and tolerance to self.<sup>16</sup>

One of the features of the genes of the MHC region is the high degree of polymorphism. The class I genes encode the antigen-presenting molecules HLA-A, -B, and -C and the class II

region genes HLA-DR, -DQ, and -DP. Both regions are located on the short arm of chromosome 6. In between the class I and II regions is the class III region, which encodes a number of genes also involved in the immune response, such as the genes for the complement factors C2 and C4 and factor B and that for the cytokine TNF- $\alpha$ . There is evidence to support the hypothesis that natural selection acts to maintain MHC polymorphism for several reasons. First, unusual allelic frequency distributions occur at MHC loci. Second, the patterns of nucleotide substitution show an enhanced rate of non-synonymous (amino acid-altering) substitution in the codons encoding the peptide-binding region of the molecules. Third, polymorphisms at certain MHC loci are very long lasting. Fourth, introns at MHC loci are homogenized by recombination and subsequent genetic drift.<sup>17</sup> There is a considerable body of evidence to support the idea that infectious diseases are the main selection force maintaining MHC diversity.<sup>18</sup>

## Cytokines

Cytokines, produced by many immune cells, act as soluble effector and regulatory molecules. A very large number of

molecules have been described and the literature abounds with studies of association between elevation or depression of a given cytokine and disease. The fact that most cytokine genes are polymorphic has resulted in a large number of studies relating such polymorphism to susceptibility or resistance to various infections (see Table 6-4). In fact, there is considerable redundancy within the cytokine network, with circuits of cytokines acting in tandem to regulate inflammatory processes, and so studies of single cytokines can be poorly informative. Variation with cytokine genes is clearly of most interest when polymorphism is shown to have potential functional correlates, as is the case for the molecules of the MHC.<sup>19</sup>

## TECHNIQUES OF GENETIC DISSECTION

It is usual to plan DNA-based dissection of the host response to infection on knowledge of the inheritance of a trait from studies of genetic epidemiology. For example, the association of a particular genotype or phenotype with geographic areas that are, or have been, epidemic for a particular disease strongly suggests a genetic component. A good example is thalassemia, a condition largely found in the tropics but also in Mediterranean countries (e.g., Italy and Cyprus) that have until the mid-20th century been endemic for malaria. One of the earliest such “micromapping” studies carried out was on the island of Sardinia, where a decrease in the frequency of thalassemia and G6PD deficiency coincided with increasing altitude, and malarial transmission was also reduced.<sup>20</sup> Reciprocally, a high frequency of allelic variants conferring susceptibility rather than resistance may be expected to be found in areas that until recently have not been exposed to a specific pathogen.

### Association Studies

In case-control studies, people with and without a particular genotype are compared with respect to a number of variables, such as whether they are infected or not, have a higher or lower parasite load, suffer a particular form of the disease, or die or not. An early example of such a study is that of Allison,<sup>21</sup> who determined that normal (AA) controls were more likely to have parasitemia with *Plasmodium falciparum* than people with sickle cell trait (AS). Unfortunately, case-control studies are most susceptible to errors in study design, the most frequent of which is inadequate power (i.e., insufficient numbers). Another pitfall lies in the choice of the control group. For example, regarding malaria, members of a control group of mild asymptomatic cases recruited during the period of a study may, during subsequent infection, develop severe disease. The incidence of some infectious diseases may be related to age and sex and so it is important in these cases to match controls appropriately for age and sex. A third problem is that although association studies can be performed for any DNA polymorphism, they are most meaningful when applied to functionally significant variations in genes that have a clear biologic relation to the trait. Thus, red blood cells containing hemoglobin S reduce parasite growth and multiplication possibly because of leakage of potassium, induction of early sickling, or premature removal of infected red blood cells.<sup>22</sup> Case-control studies are also affected by population admixture. Thus, if a study incorporates a population that is a mix of ancestrally distinct populations that have differing allele

frequencies and disease prevalence, false-negative or -positive results may arise. For the previous reasons, findings are often not replicated between studies, and confidence in an association increases if it can be reproduced widely.

A total of 1.42 million single nucleotide polymorphisms (SNPs) exist in the human genome.<sup>23</sup> As high throughput typing techniques develop, there is increased power to detect both spurious and meaningful associations. Statistical handling of large amounts of data will need to be rigorous. Analysis may also better reflect the underlying biological significance of variation. One nascent area is the testing of haplotypes across genes, rather than isolated SNPs within them, for association with infectious disease.<sup>24</sup> Another interesting approach is to relate not the frequency of a single polymorphism within a gene to disease susceptibility but the overall frequency of all polymorphisms within a gene to susceptibility.<sup>14</sup>

### Allele-Sharing Methods

A common method compares the observed and expected distributions of the number of alleles between siblings (sib pair analysis). Siblings can share none, one, or two alleles, with an expected proportion of 1:2:1 in the absence of linkage. Increased sharing of an allele would indicate selection. Such an approach has been successfully used in type 1 diabetes. It is a suitable method for microsatellite-based or SNP-based genome mapping and is increasingly applied to a number of common infectious diseases in humans. The results of such studies are then related to the completed human genome and databases of known polymorphisms to identify candidate genes. Further DNA sequencing may be necessary to detect previously undetected polymorphisms.

### Linkage Analysis

Gene loci are said to be linked if their alleles do not show independent segregation, implying that the linkage may have some selective advantage. Linkage analysis provides the methodology to quantitate this phenomenon. The application of this method to complex traits is problematic because it necessitates precise modeling. Nevertheless, it has been used in an instance in which simple Mendelian inheritance was suspected. The discovery and cloning of SLC11A1 (formerly referred to as Nramp-1), the product of the *Bcg/Ity/Lsh* locus on chromosome 1 in the mouse and associated with susceptibility to experimental Bacille Calmette-Guérin infection, leishmaniasis, and salmonellosis, created excitement in the field of host genetics and susceptibility to infection.<sup>25-27</sup> The human SLC11A1 is on chromosome 2 but two whole genome-based analyses have not linked SLC11A1 to tuberculosis.<sup>28,29</sup> The fact that some, although not all, association studies have related polymorphism in SLC11A1 to tuberculosis may reflect the greater power of association studies to detect relatively small effects.<sup>30-33</sup> The transmission disequilibrium test (TDT) tests for both linkage and association in families. Although developed to test for linkage in the presence of association, it is increasingly applied to test for association in the presence of linkage. The TDT tests for distortion in transmission of alleles from a heterozygous parent to an affected offspring. A variant that requires a greater study size is the sibTDT, in which unaffected siblings replace the parents. An elegant example of the use of an association study

**Table 6-2** Novel Genetic Immunodeficiency Syndromes That Predispose to Intracellular Infection

Molecule	Phenotype	Mutation	References
IFN- $\gamma$ receptor I	Severe atypical mycobacterial infection	Point mutation at nucleotide 395 that introduces a stop codon	116
IFN- $\gamma$ receptor II	<i>M. fortuitum</i> and <i>avium</i> infection	Homozygous dinucleotide deletion at nucleotides 278 and 279, resulting in a premature stop codon	142
IL-12p40	BCG and <i>Salmonella enteritidis</i> infection	Large homozygous deletion	143
IL-12 $\beta$ 1 receptor subunit	Severe mycobacterial and salmonella infections	A variety of missense and deletion mutations	143, 144
Stat-1	Disseminated BCG or <i>M. avium</i> infection	Point mutation at nucleotide position 2116	145

confirmed by an independent TDT analysis relates a SNP at position +874 in the interferon- $\gamma$  (IFN- $\gamma$ ) gene to susceptibility to tuberculosis in the Cape colored population in South Africa.<sup>34</sup>

### INHERITED CONDITIONS PREDISPOSING TO INFECTIOUS DISEASE

A number of well-characterized genetic defects that predispose to infection have been characterized at the molecular level (see Table 6-1). In general, these predispose to severe sepsis and the mutations responsible are so deleterious that they do not persist in populations at other than a minute frequency. The occurrence of such diseases in the tropics is not well documented; thus, their inclusion in a textbook of tropical medicine may be questionable. However, in the past few years major advances in our understanding of immunity to common intracellular pathogens has derived from the analysis of very small numbers of patients (often children) with severe

recurrent atypical mycobacterial or *Salmonella* infections. Such individuals have been shown to have mutations in the IL-12- and IFN- $\gamma$ -driven type 1 cytokine pathway (Table 6-2). This knowledge has prompted the search for less deleterious variants in these genes that may predispose to intracellular infections within populations.<sup>34,35</sup> Thus, a remarkable link exists between the molecular analysis of rare severe childhood infections in developed countries, understanding immunity, and defining genes within which variation may predispose to common infections in the tropics.

### STUDIES ON THE GENETIC INFLUENCE OF INFECTIOUS DISEASE IN HUMANS

Table 6-3 shows some HLA associations with infectious disease in humans. Table 6-4 shows non-MHC and class III MHC genes with allelic variants that have been associated with infectious disease. This is intended to be illustrative of

**Table 6-3** Summary of Some Reported Associations Between Major Histocompatibility Complex Alleles and Infectious Diseases

Disease	Effect	Allele(s)	Population	References
Protection				
HIV	Reduced progression	DQB1*0302, DRB1*0401	US, hemophiliacs	146
	Diminution in maternally transmitted virus	DRB1*1501	Whites, US	147
	Resistance to infection	DRB1*1300	Black and Hispanic, US

the types of relationship that have been described rather than being comprehensive. Some of the associations for individual diseases are discussed in more detail in the following sections.

### Malaria

Genetic resistance to malarial infection has, of all infections, been best characterized, largely because polymorphisms of the red blood cell membrane and the red blood cell's contents are easily recognized by relatively simple laboratory methods, such as blood group typing, enzyme assays, and hemoglobin electrophoresis (Table 6-5).<sup>4,36</sup> In 1949, J. B. S. Haldane introduced the concept of “balanced polymorphism,” whereby carriers of a recessive trait, for example, thalassemia, may be at a selective advantage of surviving severe falciparum malaria compared to

both normal people and those with severe thalassemia.<sup>37</sup> This so-called “malaria hypothesis” predicted that the frequency of thalassemia carriers would increase until offset by the resultant increase in the number of severely affected people in the population who would die prematurely, thus achieving a state of balanced polymorphism.  $\alpha$ -Thalassemia is usually caused by the deletion of one of the linked pair of  $\alpha$ -globin genes. The normal genotype is  $\alpha\alpha/\alpha\alpha$ ; heterozygotes ( $\alpha\alpha/\alpha-$ ) are clinically normal, and homozygotes ( $\alpha-/ \alpha-$ ) have a mild anemia. There is good evidence that thalassemia is maintained in Melanesia as a consequence of natural selection by, and protection from, malaria.<sup>5</sup> This may be a result of altered plasmodial surface antigen expression in thalassemic cells.<sup>38</sup> It was thus somewhat surprising that in Espiritu Santo (one of the islands of Vanuatu), the incidence of both the less severe vivax and falciparum

**Table 6-4** Non-MHC and Class III MHC Genes with Allele-Specific Associations with Infection

Gene	Allele	Effect	References
Cytokines and Chemokines			
TNF- $\alpha$	TNFA*2[-308]	Increased severity of falciparum malaria, meningococcal disease, and mucocutaneous leishmaniasis	116, 155, 156
IL-1 complex	IL-1Ra A2-ve/IL-1 $\beta$ +3953) A1 +ve	Increased DTH and pleural tuberculosis	19
IL-8	Haplotype 2	Increased susceptibility to RSV infection	24
IL-10	ATA haplotype	Spontaneous clearance or more rapid fibrosis	99, 100
RANTES	In1.1C allele	Accelerated progression of HIV	57
SDF-1	3' A/3' A	Delayed or accelerated progression of HIV	55, 56
Interferon- $\gamma$	+874 SNP	Increased susceptibility to tuberculosis	34
Receptors			
CCR2	64I allele	Slower progression of HIV	53
CXP5	32-bp deletion	Slower progression of HIV	52–54
	CCR5P1 haplotype	Rapid progression of HIV	55
IL-12 receptor $\beta$ 1	R214-T365-R378 allele (2)	Increased susceptibility to tuberculosis	35
Vitamin D receptor	VDR tt and ff genotypes	Resistance to tuberculosis and hepatitis B	29, 71
TLR4	Multiple	Increased susceptibility to meningococcal disease	14
TLR5	392 stop codon	Increased susceptibility to Legionnaires' disease	15
Various			
SLC11A1	Various	Susceptibility to tuberculosis	31–33
Haptoglobin	2-2	Increased severity of pulmonary tuberculosis	63, 69, 70
Mannan binding lectin (MBL)	Codon 52, 54, and 57 variants	Increased risk of meningococcal disease and pneumococcal disease; decreased risk of tuberculous meningitis	106, 141

**Table 6-5** Red Cell Variants Believed to Provide Protection Against Malaria

Variant	Distribution	Postulated Mechanism	References
Hemoglobinopathies			
Hb S	Sub-Saharan Africa, Indian subcontinent	Premature removal of infected cells, reduced multiplication, induced sickling	22
Hb C	West Africa	Impairment of merozoite release	157
Hb E	Southeast Asia	Increased phagocytosis	158
Hb F	Global	Sensitivity to oxidant stress	159
$\alpha$ -Thalassemia	Global in malaria endemic areas	Increased IgG binding, sensitivity to oxidant stress	5, 38
$\beta$ -Thalassemia	Mediterranean, Southeast Asia, West Africa	Increased IgG binding, sensitivity to oxidant stress	160
Red cell enzymes			
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	Worldwide	Sensitivity to oxidant stress	40
Pyridoxal kinase	Sporadic	Unknown	161
Red cell membrane			
Melanesian (band III) Ovalocytosis	Melanesia	Reduced invasion	162
Duffy antigen negativity	West Africa mainly; also East Africa	<i>Plasmodium vivax</i> only, failure of invasion	163
Blood group O	Worldwide	Poor rosette formation	164
Glycophorin B deficiency	West Africa	Decreased invasion	165

malaria in homozygous thalassemic children aged 0 to 4 years was approximately twice as high as in  $\alpha\alpha/\alpha\alpha$  children.<sup>39</sup> The incidence of the rarely severe vivax malaria was particularly high in thalassemia homozygotes younger than 30 months old. The authors postulated that infection by vivax malaria at this age, perhaps because thalassemia is characterized by a mild increase in the number of immature red blood cells (reticulocytes), which are the preferred red blood cell habitat of *P. vivax*, may result in cross-reactive immunity to the lethal effects of *P. falciparum*. Another possibility is that the *P. falciparum* strains present on the island studied may be less virulent, because it is certainly the case that severe falciparum malaria on this island is much less frequent than elsewhere in the world.<sup>39</sup> In another case-control study, the protection of both G6PD-deficient hemizygotes (males) and heterozygote females against falciparum malaria, in both west and east Africa, was demonstrated, resolving an age-old debate on the importance of this genotype in the face of severe falciparum malaria.<sup>40</sup>

Protection against two life-threatening manifestations of malaria, cerebral disease and anemia, is associated in The Gambia with the class I antigen HLA-B53. Protection against anemia only was conferred by the class II extended haplotype DRB1\*1302-DQB1\*0501.<sup>6</sup> Because HLA-B53 is rare in populations not exposed to malaria, it was proposed that the frequency in The Gambian population studied was due to natural selection. Because red blood cells do not express class I molecules, the site of cytotoxicity is presumably the infected liver cell. Cytotoxic cells do contribute to antimalarial immunity and it was possible to show that a nonamer peptide eluted from the HLA-B53 molecule was able to induce such responses in people exposed to malaria.<sup>41</sup> However, it has been known for more than 30 years that malarial parasites undergo antigenic variation, which can be provoked by the host immune response.<sup>42,43</sup> *Plasmodium falciparum* has no known animal reservoir and thus it is pertinent to bear in

mind that the human immune response is conversely almost certainly a powerful selective force on the parasite. Integrated analysis of host and parasite variation is complex but almost certainly will offer powerful future insights.<sup>44</sup> The cytokine TNF- $\alpha$  is encoded by a gene within the MHC class III region on the short arm of chromosome 6 and transcription is under the control of a promoter that lies 5' to the structural gene. TNF- $\alpha$ , especially when produced in excess, is implicated in the pathogenesis of a number of severe infections, including gram-negative sepsis, tuberculosis, human immunodeficiency virus (HIV) infection, and malaria. Homozygosity for a polymorphism in the promoter region, involving a guanine-for-adenine substitution at position -308 relative to the start codon, is associated with a 7.7 times increased risk of death from cerebral malaria.<sup>7</sup> The functional significance of this polymorphism, however, is controversial. Although it has been shown that people both homozygous and heterozygous for this polymorphism produce significantly more TNF- $\alpha$  in response to lipopolysaccharide (LPS) in vitro,<sup>45</sup> paradoxically two studies of the effect of this polymorphism on transcription showed no effect.<sup>46,47</sup> Recently, a number of non-MHC and class III MHC genes with allele-specific associations with malaria have been described and more examples of these will no doubt follow (Table 6-6). Some of these genetic variants have shown protection against severe disease and others increased susceptibility that may vary, for instance, with the malarial disease phenotype or the population studied, and they would fail to recognize an advantage in the face of some other as yet unidentified selection pressure.

### Human Immunodeficiency Virus

There is variability in the natural history of HIV infection. Three categories of infected people have attracted attention: those who progress rapidly, long-term nonprogressors (LTNP),

**Table 6-6** *Examples of Non-MHC and Class III MHC Genes with Allele-Specific Associations with Malaria*

Gene	Variant	Effect	Population	References
Protection				
CR-1	CR1 deficient	Severe disease	Papua New Guinea	166
Fcγ receptor IIa (CD32)	R131 allele, rather than the RR131 genotype	Severe disease	Children in The Gambia	167
Cd36 gene	Heterozygosity for a non-sense mutation	Severe disease	Kenyan children	168
Intercellular adhesion molecule-1 (ICAM)	ICAM-1 Kilifi (change from Lys to Met in the loop that interacts with parasitized red blood cells)	Severe disease	Children in Gabon	169
CD40 ligand (CD40L)	Males hemizygous for the CD40 L-726C (not significant in females)	Severe disease	The Gambia	170
Nitric oxide synthase 2 gene (NOS2)	NOS2 (Lambarene) (NOS2-G954C)	Severe and mild disease	Gabon	171
Increased susceptibility				
TNF-α	TNFA*2 [-308].	Increased severity of cerebral malaria	Children in The Gambia	156

TNF (promoter region)	OCT-1-binding genotype	Increased susceptibility to cerebral malaria	Children in The Gambia	173
Fcγ receptor IIa (CD32)	HH131 genotype	Severe disease	Children in The Gambia	167
Inducible nitric oxide synthase promoter	Longer forms of CCTTT microsatellite repeat	Severe disease	Adults in Thailand	174
Haptoglobin	Hpl-1	Severe disease	Children in Ghana	175
No effect				
Complement receptor 1 (CD35)	Gene underlying the Knops antithetical antigens S11/S12 and McC(a)/McC(b)	No association	Children in The Gambia	176

and people who are very likely to have been exposed but who do not seroconvert. Initial interest centered on the MHC with reports that rapid progression is associated with the HLA-A1-B8-DR3 extended haplotype.<sup>48,49</sup> It has been reported that the HLA A\*0205 is associated with resistance against infection,<sup>50</sup> an observation that fits with a number of reports that ascribe protection against HIV infection to antiviral CD8+ T cells.<sup>51</sup>

The phenomenon of heavily exposed but persistently uninfected people also came to prominence when the coreceptors for HIV infection were described in the mid-1990s. For T-tropic viruses the coreceptor is CXCR-4, and CCR-5 is the coreceptor for M-tropic viral strains. A defective CCR-5 allele, which contains a 32-base pair deletion, prevents expression of CCR-5 at the cell surface. Homozygotes for this mutation are resistant to HIV infection, and infected heterozygotes have slower disease progression, a finding that has been widely reproduced.<sup>52–54</sup> Attendant on the discovery of CXCR-4 and CCR5 as the coreceptors for HIV, a large number of studies have also examined genetic variants in both the chemokine ligands and receptors on susceptibility and the progression of HIV. Thus, a multisite haplotype of the CCR5 regulatory region containing a promoter allele, CCR5P1, that increases CCR5 expression is associated with rapid progression to AIDS, particularly in the early years after infection.<sup>55</sup> HIV-1-infected individuals carrying the CCR2-64I allele progressed to AIDS 2 to 4 years later than individuals homozygous

for the common allele.<sup>53</sup> Varying findings, however, have been made with respect to the ligands. For example, a common polymorphism SDF1-3'A exists in the 3' untranslated region of the stromal-derived factor 1 gene, a ligand of CXCR-4. In the homozygous state, SDF1-3'A/3'A is reported to delay or accelerate the onset of AIDS.<sup>55,56</sup> Similar complexity is revealed by the finding that the downregulating RANTES In1.1C allele, which is in linkage disequilibrium in African Americans with a weaker upregulating RANTES promoter allele (-28G), associates with rapid progression.<sup>57</sup> However, the -28G promoter allele was not associated with rapid progression in a European cohort.<sup>58</sup>

### Tuberculosis

Environmental factors are clearly predominant in the development of tuberculosis, so it may be concluded that the role of genetic susceptibility may not be great. However, there are several lines of evidence to suggest that host genes contribute to outcome. There is moderate disease discordance between dizygotic and monozygotic twins.<sup>59,60</sup> The relationship between the human SLC11A1 gene and tuberculosis has already been discussed. In addition, an association between pulmonary disease and HLA-DR2 has consistently been reported.<sup>3,61–64</sup> The two largest studies that typed class I alleles failed to detect any association,<sup>62,65</sup> although one study has reported increased frequencies of A3-like supertypes and

decreased frequencies of A1-like supertypes in tuberculosis patients.<sup>66</sup>

Two whole genome scans have detected moderate (LOD scores <3) linkage of tuberculosis to different chromosomal regions. In Africa, linkage was found to chromosomes 15q and Xq and in Brazil to chromosome 17q11.2.<sup>28,29</sup> Chromosome 17q11.2 has some interesting candidates, including a number of chemokine genes and the inducible NO synthase gene (NOS2). The link to chromosome Xq is also interesting because a male excess of tuberculosis is reported in many populations. Fine mapping has the potential to refine these linkages.<sup>67</sup> However, the lack of a clear major locus for tuberculosis in these studies raises the possibility that most of the genetic component of susceptibility to tuberculosis is dispersed among many loci.<sup>68</sup>

Of the non-MHC genes, there is a substantial body of non-English literature relating haptoglobin 2-2 to the severity of pulmonary tuberculosis, an association that has been reproduced in Africa.<sup>63,69,70</sup> The basis for this is unknown. Homozygotes for a noncoding polymorphism at codon 352 (genotype tt) of the vitamin D receptor gene were significantly underrepresented among Gambians with tuberculosis, an association that was supported by analysis of a separate population of Asians in West London.<sup>29,71</sup> The study from London made a rare attempt to analyze gene–environment interaction by concurrent determination of serum vitamin D levels. Acquired deficiency of vitamin D was far more powerfully associated with tuberculosis than genetic variation in its receptor. Both studies are biologically plausible because 1,25-dihydroxyvitamin D<sub>3</sub> is reported to decrease the intramacrophage growth of *Mycobacterium tuberculosis*.<sup>72</sup>

Research on genetic susceptibility to tuberculosis presents typical, and some exceptional, difficulties with respect to phenotyping. Thus, the determination of susceptibility to develop tuberculosis may best be addressed in children, who are highly susceptible to progression to primary disease. However, culture confirmation of active disease in children is rare and few studies have therefore addressed this with confidence. Because most tuberculosis infection in adults is latent, the phenotyping of control subjects for association studies also presents difficulties. Should controls be tuberculin skin test positive and thus likely to be infected and assumed resistant, or should they be negative? Few, if any, studies have addressed this in detail. The clinical manifestations of reactivation (the most common disease pattern of adults) are quite varied. One possibility is that polymorphic genes affect disease pattern, and some studies have suggested evidence of this.<sup>19,29,73</sup>

## Helminthic Infections

An exhaustive and scholarly review of human genetic susceptibility to helminth infection has been published.<sup>74</sup> Two features of helminth infections have attracted genetic study. The first is that, within populations, helminths tend to be overdistributed (i.e., a few people harbor high parasite burdens). Notwithstanding the environmental, behavioral, and parasitic factors that contribute to this feature, there is evidence that the intensity of helminth infection is partially under genetic control. The second feature is that sequelae, particularly of invasive helminth infection, arise because of immunopathology. Thus, fibrosis in schistosomiasis or the dichotomy between

microfilaremia or hypersensitivity in filarial infection may have genetic correlates. In particular, a great deal of attention has been paid to the possibility that variants of genes that predispose to atopy protect against helminths. Unfortunately, this exercise has generated as much hot air as hard data.

In contrast, two whole genome-based linkage analyses have productively related the intensity of helminth infection to specific chromosomal regions. In a landmark study of a quantitative trait, microsatellite mapping of 11 informative families in Brazil indicated that the control of intensity of *Schistosoma mansoni* infection mapped to a single region of chromosome 5, most closely to the colony-stimulating factor receptor 1 gene (CSF1R) but also to a region containing the genes for the important type 2 cytokines IL-4, -5, and -13.<sup>75</sup> Also, the intensity of *Ascaris* infection was linked to genes on chromosomes 1 and 13, with the most plausible candidate being the B lymphocyte stimulator protein (BlyS).<sup>76</sup>

Hepatosplenic schistosomiasis is believed to be largely due to the immune response to egg antigens, and there have been a number of studies on the role of HLA. Studies from Egypt and a single study from South America have consistently related HLA-B5 to hepatosplenomegaly in *S. mansoni* infection.<sup>77,78</sup> Studies of *Schistosoma japonicum* infection tend to be small, yielding multiple HLA associations, although in the largest of these HLA-B44 was a risk factor for the development of hepatosplenic disease.<sup>79</sup> In a more recent molecular analysis restricted to class II alleles, it was reported that hepatosplenic disease is associated with DQB1\*0201.<sup>80</sup>

Lymphatic filariasis caused by *Wuchereria bancrofti* and *Brugia malayi* is characterized by a spectrum of manifestations from asymptomatic microfilaremia to deforming elephantiasis. Tissue damage in elephantiasis is suspected to be immune mediated. In a study of patients with filariasis, the frequency of HLA-B27 and -DQ5 was increased and that of HLA-DR3 decreased in patients with elephantiasis compared to other patients older than age 45.<sup>81</sup> DQB1\*0501 has also been associated with patients with localized, as opposed to generalized, onchocerciasis.<sup>82</sup>

## Other Diseases

### Leprosy

The polar spectrum of clinical leprosy offers an opportunity to investigate the effect of genetic factors on disease expression, but most effort has been directed toward determining susceptibility. An early application of transmission disequilibrium testing suggested linkage of susceptibility to the MHC locus on chromosome 6.<sup>83</sup> At least five studies have indicated an association between leprosy and HLA-DR2, which is strongest for tuberculoid disease. In two studies from India in which molecular typing methods were used, it appears that tuberculoid leprosy associates with DRB1\*1502 and lepromatous disease with DRB1\*1501.<sup>84,85</sup> However, others concluded that susceptibility to leprosy per se is probably not controlled by HLA-linked genes.<sup>86</sup>

Remarkably, three whole genome scans for leprosy susceptibility in different populations have been reported with entirely different results. The first to be published was a study of the genomes of 224 families from South India containing 245 independent affected sibpairs, mainly with paucibacillary leprosy.

Linkage was found to multiple markers on chromosome 10p13.<sup>87</sup> A later study in Vietnam reported linkage to chromosome 6 but not the MHC, specifically to 17 markers located in a block of approximately 80 kilobases overlapping the 5' regulatory region shared by the Parkinson's disease gene *PARK2* and the coregulated gene *PACRG*.<sup>88</sup> The same study reproduced the association in a large case-control analysis in Brazil. Also in Brazil, weaker linkage of leprosy to markers on chromosome 17q has been reported.<sup>28</sup> The decaying genome of the leprosy bacillus appears to contain close to the minimum set of genes necessary for mycobacterial survival and thus does not have much scope to vary between populations.<sup>68</sup> How these disparate whole genome scan results will be reconciled remains to be seen.

## Hepatitis B and C

A considerable number of studies have been conducted on this subject and on susceptibility to develop hepatocellular carcinoma, which is associated with these infections. In addition, a number of small-scale studies have attempted to associate the response to antiviral therapy with genetic factors. Mutations in codons 52, 54, or 57 in exon 1 of the MBL gene reduces serum MBL levels and may be associated with an opsonic defect. An early analysis showed that a mutation in codon 52 is more common in white, but not Asian, patients with chronic hepatitis B virus (HBV) infection. However, the codon 54 mutation, which in the same study was associated with a greater depression of serum MBL, was not associated with disease.<sup>89</sup> Subsequent studies were not able to associate MBL mutations with hepatitis B.<sup>32,90</sup> An early study associated HLA-DRB1\*1302 with transient HBV infection in Gambian adults and children.<sup>91</sup> This association has been replicated in other populations, although a greater protective effect of HLA A\*03 was reported for Caucasians.<sup>92,93</sup>

Several studies have reported an association of the HLA DQB1\*0301-DRB1\*11 extended haplotype with self-limiting HCV infection.<sup>71,94-96</sup> Interestingly, this haplotype is associated with the maintenance of a multispecific CD4+ T helper response to HCV that persists during and after therapy.<sup>97</sup> There is also a trend toward less severe disease with DRB1\*11 alleles. Studies of extrahepatic manifestations of chronic HCV have shown an association between DQB1\*11 and DRB1\*03 with the formation of cryoglobulins.<sup>98</sup> A number of cytokine gene polymorphisms have been studied in the context of HCV infection with variable results. For example, the IL-10 ATA haplotype was reported as more frequent in patients with spontaneous HCV RNA clearance, whereas in another study this haplotype was more frequent among patients with rapid fibrosis.<sup>99,100</sup>

## Meningococcal Disease

Most individuals acquiring new strains of meningococci, despite lacking specific antibody for several weeks, do not develop invasive disease following nasopharyngeal acquisition of new strains of meningococci.<sup>101</sup> This suggests that innate immune mechanisms are effective in containing the organism. Host molecules relevant to innate immunity to meningococci include plasma proteins such as complement, mannose-binding lectin, and C-reactive protein, as well as the extensive range of

pattern recognition receptors on cell surfaces, such as the TLRs, CD14, and mannose receptors.

Deficiency in terminal components of the complement pathway and properdin with recurrent meningococcal disease are well recognized<sup>102-104</sup> and are shown in Table 6-1. Individuals possessing functional variants in the gene for mannose-binding lectin<sup>105</sup> that lead to reduced plasma concentrations of the protein have increased susceptibility to meningococcal disease.<sup>106</sup>

The host innate immune response to invading microorganisms is triggered following recognition of common structural motifs present on bacteria and viruses through a range of pattern recognition receptors.<sup>107-109</sup> Endotoxin [lipopolysaccharide (LPS)] is able to trigger innate immune responses following recognition by a number of host proteins and surface receptors, including the family of TLRs and the CD14 molecule.<sup>109,110</sup> The importance of TLRs in containing gram-negative organisms was first identified in mice with mutations in the LPS locus.<sup>111</sup> LPS receptor-deficient mice (homologous to TLR-4 deficiency in humans) are unable to respond to bacterial endotoxin and show enhanced susceptibility to infection with *Salmonella*, *Neisseria*, *Escherichia coli*, and other gram-negative organisms.<sup>110-112</sup> An excess of rare TLR-4 coding changes was found in patients with meningococcal disease compared to controls utilizing complete sequencing of the TLR-4 gene ( $p = 2 \times 10^{-6}$ ; odds ratio, 27).<sup>14</sup> This study suggests a critical role for endotoxin sensing in containment of meningococcal disease. TLR-4 is only one of a large number of proteins involved in the detection of endotoxin and other bacterial structures; these include at least nine other proteins in the family of TLRs, CD14, and the accessory proteins including MYD88, MD2, as well as the downstream regulators of cellular activation.<sup>14,109-113</sup> Some or all of these may contribute to the recognition of gram-negative organisms and the activation of defensive host inflammatory responses.

An extensive body of evidence suggests that patients with fulminant and fatal meningococcal disease have an excessive and uncontrolled inflammatory response often under genetic control, with activation involving both cellular and non-cellular inflammatory pathways.<sup>114,115</sup> Following the initial report that heterozygosity for the -308 promoter polymorphism in the TNF gene was associated with an increased (2.5 times) risk of death in meningococcal disease,<sup>116</sup> an association between outcome of meningococcal disease and other polymorphisms in the IL-10 and IL-1 pathway has also been reported.<sup>117,118</sup>

Purpura fulminans is the most dramatic complication of meningococcal sepsis, leading to peripheral gangrene and often requiring amputation of limbs and digits. Predisposition to purpura fulminans may also have a genetic basis. A functional polymorphism in the plasminogen activator inhibitor gene is associated with meningococcal outcome.<sup>119</sup> The same applies to the factor V Leiden gene.<sup>120</sup> Patients possessing the 4G allele within the *PAI-1* promoter gene produce higher levels of plasminogen activator inhibitor but are at increased risk of death, confirmed in a much larger subsequent study.<sup>121</sup> These genetic differences in the key regulators of the antithrombotic and thrombolytic pathways likely explain the occurrence of purpura fulminans associated with meningococcal disease.

## CLINICAL RELEVANCE

For most practitioners of tropical medicine, the association of disease with genetic polymorphisms may appear attractive intellectually but of very little clinical relevance. We are only on the fringe of discovery of genetic factors influencing host resistance or susceptibility to infection. However, at this relatively early stage, some of the following observations, particularly relating to malaria, have immediate clinical implications and others have more importance for the future:

- Nonimmune carriers of the hemoglobinopathies remain at risk of acquiring malaria. The protection offered by “protective traits” is only relative, and in any case applies only at the population level. Advice to these individuals with regard to antimosquito measures and other precautions to avoid malaria is in no way different from advice to normal people. Patients with sickle cell disease rather than sickle cell trait are at particular risk if they acquire severe malaria.
- People with G6PD deficiency need to avoid a number of potentially harmful oxidant drugs. Primaquine, used in the eradication of the exoerythrocytic forms of vivax and ovale malaria, is one example of a relatively potent oxidant drug that can induce severe hemolysis in a G6PD-deficient person. Chloroquine, on the other hand, is a relatively weak oxidant and only needs to be avoided in severe G6PD deficiency or in people who have had hemolysis in response to the drug in the past. This is one of the best examples of the new area of “pharmacogenetics.”
- Errors in determining drug sensitivity of malarial parasites: Parasites cultured in hemoglobin S (Hb S)-containing red blood cells may erroneously appear to be chloroquine resistant. The same parasites, if grown in cells containing Hb A, appear to be sensitive.
- Gene therapy: If a disorder can be shown to be caused, or highly influenced, by a single gene, it may be possible to “replace” the defective gene. An approach to this type of therapy has been described for X-linked severe combined immunodeficiency.<sup>122</sup> This type of approach will not, however, be applicable to diseases such as malaria or tuberculosis, in which susceptibility is likely to be influenced by a large number of genes.
- Vaccination: “Reverse immunogenetics” is the process by which likely T-cell epitopes are either deduced or eluted from MHC molecules shown to be associated with protection. This approach has been used in the identification of peptide epitopes possibly suitable as components for vaccines against malaria. This approach is being applied to a number of other infections. However, it must be borne in mind that adverse effects, as well as protection, can result from inappropriate activation of T cells in many diseases caused by intracellular parasites, emphasizing that caution needs to be taken with this approach.
- Identification of the genetic contribution to complex diseases will lead to an increased understanding of the pathogenesis that will have positive consequences for both diagnosis and treatment.

# Disease Eradication and Control

DONALD A. HENDERSON

## INTRODUCTION

In 1980, the achievement of smallpox eradication stimulated widespread interest in eradication as public health policy. The smallpox program's success dispelled doubts as to the theoretical feasibility of disease eradication itself and raised hopes that other programs might soon follow. Undertaking intensive, short-term disease control programs with the objective of eliminating a disease has been highly attractive to politicians and health staff alike. The costs of these undertakings are anticipated to be repaid by sharply curtailing preventive measures or stopping them altogether when eradication is achieved.

Smallpox eradication has been succeeded by globally coordinated eradication programs for poliomyelitis<sup>1</sup> and dracunculiasis (Guinea worm infection).<sup>2</sup> Meanwhile, many other diseases have been and continue to be proposed as possible candidates for eradication.

In tropical and industrialized countries alike, there are many who now conceive of disease eradication strategies as a major theme for disease control over the coming decades. The reality of these assumptions must be critically examined because, as history has shown, the price of failed eradication campaigns has been high.

## PAST ERADICATION CAMPAIGNS

Many have forgotten that the smallpox eradication campaign was only one in a series of major eradication efforts that date back to early in the 20th century. The possibility of disease eradication was originally suggested by the dramatic successes achieved by early community-wide preventive measures such as vaccination, improved sanitation, nutrition, and vector control. As early as 1888, Charles Chapin, one of America's leading figures in public health, rashly proposed that preventive measures for any disease, if diligently applied, could potentially lead to eradication of that disease.<sup>3</sup> Although Chapin himself did not sustain this argument, others did and most persuasively.<sup>4-6</sup> Thus, throughout the last century, one eradication program after another has been launched, each with lofty expectations and considerable fanfare. These programs, in both their successes and failures, have played important roles in shaping broader public health policies in many countries. None, other than for smallpox, has yet proved successful. In most instances, unfortunately, the failed

eradication efforts have left little as a legacy, despite substantial long-term investments in time, energy, and resources. Most of the initiatives have been long forgotten.

The first planned program to eradicate a human disease dates from 1909 when the Rockefeller Foundation launched a hookworm eradication campaign, first in the United States and later extending it to 52 countries on six continents.<sup>7</sup> Its strategy was based on mass screening of children for hookworm infection, their treatment with drugs, and the construction of sanitary facilities. The strategy and the glowing predictions for success were rooted primarily in evangelistic optimism. Nearly 15 years elapsed before the program was critically evaluated. The evaluation showed that the campaign, in fact, had not significantly reduced hookworm infection rates anywhere.<sup>8</sup> The program died a quiet death.

Meanwhile, beginning in 1915, the Rockefeller Foundation launched a yellow fever eradication campaign with the announced expectation of eradicating the disease from the Americas within five years.<sup>9</sup> The foundation anticipated that similar programs in Africa would soon follow. The campaign strategy called for reducing the density in cities and towns of the vector mosquito, *Aedes aegypti*, whose breeding sites were in and near houses. Experience had shown that when mosquito densities were lowered sufficiently, the yellow fever virus ceased to be transmitted.

The campaign proved to be far more difficult and costly than had been anticipated, and so it never extended beyond the Americas. It foundered, finally, when it was discovered in the 1930s that the yellow fever virus had a natural reservoir among jungle mammals, thus making eradication impossible. Abruptly, the strategy shifted to an attempt to eradicate the *A. aegypti* mosquito itself on the premise that even if the yellow fever virus continued to circulate in the jungle, it would be unable to be transmitted in urban settings.<sup>10</sup> However, the task of eradicating a well-established mosquito vector from the whole of the Western Hemisphere proved to be formidable and far beyond the scope of available technology and resources. Efforts gradually waned and finally stopped during the 1970s.<sup>6</sup>

The 1940s brought yet another eradication campaign—against yaws. This was an international effort under the aegis of the World Health Organization (WHO). National yaws programs eventually included 61 countries.<sup>11</sup> The programs sought to eliminate infection by mass screening and treatment with penicillin. After 20 years, however, the yaws program finally had to be abandoned when it was discovered that infected persons who were missed during screening and some with mild or subclinical infection permitted the yaws spirochete to continue to spread despite the best efforts of the field teams.<sup>6</sup>

Finally, in 1955, the most ambitious of all eradication schemes, for malaria, was approved by the World Health Assembly.<sup>12</sup> As with each of the preceding eradication campaigns, the decision to launch the program was more heavily grounded in visionary enthusiasm than in sound science. The malaria eradication strategy relied on the use of a new insecticide, DDT, to be sprayed on the walls of dwellings. Mosquitoes, after biting a patient, customarily settled on adjacent walls, but were killed by DDT and therefore did not further transmit infection. Over a 20-year period, more than \$2 billion was expended on national programs extending across all continents.<sup>13</sup> The programs proved to be far more complicated

and costly than anyone had anticipated. Insecticide resistance became an increasing problem. From the beginning, it had been known that for most of Africa the basic strategy would not work, in part, because of the presence of mosquito species with quite different behavioral characteristics. However, no answer to this problem was found. By the mid-1970s, yet another large and costly eradication effort had collapsed, leaving as a legacy very little compared to the magnitude of the investment that had been made.

In the 1950s and 1960s, the possibility of smallpox eradication began to be discussed, but politicians and health professionals alike were skeptical of *any* eradication effort.<sup>14</sup> Each of the preceding eradication campaigns had been optimistically launched and had persisted for some 20 to 30 years before it became apparent that the epidemiology and ecology of the respective diseases were different from what had been assumed, that the available technology was inadequate to accomplish the task, and that needed resources were, in any case, far greater than had been budgeted or were available. Not surprisingly, the World Health Assembly, in 1966, did not unanimously welcome the proposal that \$2.4 million be designated annually in the regular budget for a greatly strengthened effort to deal with smallpox.<sup>13</sup> Many delegates doubted that the eradication of any disease was possible and others simply did not want to contribute additional funds to a United Nations organization. However, after extended debate, a special smallpox program was approved, albeit by only a two-vote margin. A 10-year goal was suggested. UNICEF (United Nations International Children's Emergency Fund), however, as well as several national assistance agencies, indicated that they would not support any new eradication effort. Indeed, some countries with endemic smallpox initially chose not to participate because of doubts about eradication as a concept.

## INTEREST IN ERADICATION IS REVIVED

Over the 11-year period 1967 to 1977, smallpox was eradicated, and this was confirmed officially by the World Health Assembly in 1980. Smallpox vaccination ceased in all countries. Soon a renewed interest in disease eradication arose.

It is notable that there were features about the campaign and about smallpox itself that made eradication more feasible than for any disease previously on the eradication agenda or, for that matter, for any candidate disease.

1. Variola major, the predominant form of smallpox, had a case-fatality rate of 20% to 30% in unvaccinated persons, and being able to spread in any climate was a serious threat to both industrialized and developing countries. Essentially, all countries maintained vaccination programs of some sort whether or not they were endemic. Today, only measles, tuberculosis, and acquired immunodeficiency syndrome (AIDS) pose a threat that begins to approach that of smallpox.
2. There were no animal reservoir and no insect vectors involved in transmission, unlike the situation with malaria and yellow fever, for example.
3. Every infected person developed illness and had a characteristic rash that was readily identifiable by both villagers and health staff. Transmission occurred only during the time the rash was present. On recovery,

approximately three-fourths of those who had variola major were left with residual pockmarks on the face, and these lasted for life. Because of these factors, the presence of the virus in any geographic area could be detected readily and outbreaks contained. It was also possible to determine when smallpox infection had been present in an area during previous years, an important determination for remote areas when it became necessary to certify that eradication had been achieved.

4. Outbreaks were reasonably easy to stop. Smallpox spread comparatively slowly in a continuing chain of transmission. Normally, there was an interval of about two weeks between each new generation of cases, and those who were infected usually did not transmit infection to more than two to five additional persons, primarily relatives or close friends. Thus, when a case was detected, it was possible to stop the spread of infection by vaccinating tens to hundreds of potential contacts in an area and to trace the origin of infection to detect other possible outbreaks.
5. An inexpensive, highly thermostable vaccine provided nearly complete protection for periods of 10 to 20 years after a single inoculation. No other vaccine today approaches smallpox vaccine in terms of heat stability, and none provides greater than 95% protection with a single dose of vaccine.

All manner of diseases and conditions have been proposed for eradication since 1980.<sup>15</sup> Some of those mentioned include syphilis, tuberculosis, urban rabies, leprosy, hepatitis B, hunger, traffic accidents, measles, polio, and dracunculiasis.<sup>13,16</sup> Enthusiasm for eradication initiatives stemmed, in part, from the belief that a highly visible, widely publicized eradication target is especially attractive to politicians and the public alike and will garner substantially more funds and support than will programs intended for disease control. Proponents reason that even if programs fail, more money will have been secured for public health and that some good will have been accomplished. Memories of the failed malaria program and the damage this did to the credibility of public health have been little appreciated.

Many of the proposed initiatives for eradication are recognizably meaningless in terms of the accepted definition of eradication: "the purposeful reduction of specific disease prevalence to the point of continued absence of transmission within a specified area by means of a time-limited campaign."<sup>6</sup> Certainly, eradication has no meaning when applied to hunger or traffic accidents, for example. Objections by many to the cavalier use of the term *eradication* resulted in an even more regrettable phrase, "eradication of a disease as a public health problem." Proponents intended the phrase to mean that through control measures, the incidence of a disease would be maintained below some arbitrary level. This was an unfortunate construct, soon discarded as having little meaning. More recently, there has been a growing effort to use the term *elimination* of disease when it is clear that a high degree of control rather than eradication is sought. This term is also misleading as neither reference dictionaries nor scientists are able to distinguish *elimination* from *eradication*. In this chapter, reference is made only to disease eradication as properly defined.

## THE FEASIBILITY OF OTHER ERADICATION PROGRAMS

Despite the fact that, for eradication, there were many advantageous attributes intrinsic to both smallpox as a disease and to the program, the eradication effort barely succeeded. Financial support for the program was always precarious despite the fact that every country stood to gain substantially from its eradication. A number of the endemic countries themselves were reluctant participants and some were so torn by civil war that operations could be conducted only during brief intervals in the conflict. Despite the leadership role that WHO played, its internally fragmented leadership made coordinated program operations difficult. To eradicate any disease with less favorable characteristics than those offered by smallpox presents a formidable challenge. Nevertheless there are now two that are in operation—one for polio and one for dracunculiasis.

Polio eradication, as an objective for the Western Hemisphere, was decided on by the Pan American Health Organization in 1985 and a global program by the World Health Assembly in 1988.<sup>1</sup> The basic strategy is similar to that employed for smallpox eradication: (1) special vaccination programs to heighten immunity and (2) surveillance programs to assure that all possible cases of polio are reported, competently investigated, and confirmed. Two special features of the vaccination programs deserve note: (1) national immunization days (NIDs) and (2) “mopping-up campaigns.” Countries have scheduled NIDs twice each year during which all children, usually those less than 4 years old, have been vaccinated at collecting points during the cooler months of the year. This is the time of year of the lowest prevalence of enteric viruses that could block growth of the live oral polio vaccine in the intestine. Mopping-up campaigns have been conducted when polio incidence has fallen to very low levels. Such campaigns consist of door-to-door vaccination in the poorest, most densely crowded areas of the country. These are the areas usually found to harbor persistent endemic poliovirus spread.

Five problems have made the eradication of polio far more difficult than was smallpox eradication:

1. In developing countries, polio is nowhere near the problem posed by diseases such as malaria, tuberculosis, and measles. Not surprisingly, few countries were engaged in control programs prior to the advent of the eradication effort. Smallpox, by contrast, was the most feared of all the infectious agents, and all countries had vaccination programs of some sort before global eradication began.
2. In developing countries, polio is far more contagious than smallpox, and thus it is far more difficult to stop its spread. Virtually all children acquire polio infection by 3 to 4 years of age, whereas with smallpox, even in densely populated heavily endemic countries such as India, only 30% of cases were in children younger than 5 years.
3. Polio vaccine is very thermolabile and much less antigenic than smallpox vaccine. Logistically problematic “cold chains” have had to be developed to assure its potency at the point of delivery. In contrast, the smallpox vaccine was stable for 30 days or more even at temperatures of 37°C. Where five or more doses of

polio vaccine were normally required to provide protection to 90% or more of recipients, successful vaccination rates for a single smallpox vaccination were consistently more than 95%.

4. Polio surveillance was far more difficult, requiring, as it did, that stool specimens be obtained from all patients within two weeks of illness onset in order to be able to differentiate polio cases from those experiencing paralysis due to other causes. Obtaining, transporting, and identifying specimens posed formidable challenges. In contrast, laboratory confirmation of smallpox cases was seldom needed.
5. A key factor in achieving smallpox eradication was the ability to rapidly stop the spread of disease by vaccinating contacts and neighbors of cases. This was possible because every infected person was readily identifiable and the contacts protected before the disease could spread. For polio, there are perhaps 200 or more infected but asymptomatic individuals for every paralytic case. Thus, a targeted containment program is impossible to execute.

Two impediments to eradication, which were discovered only after the eradication program began, raised questions about its feasibility.<sup>17,18</sup> These impediments relate to the behavior of the attenuated polioviruses, which comprise the live oral polio vaccine (OPV). OPV is the preferred vaccine in most countries, especially in the developing world, because it is considerably less expensive than the inactivated vaccine; it is easier to administer; and it spreads readily in households, serving to protect both the vaccinees and their contacts.<sup>19</sup> Because it quickly provides protection against acquiring and transmitting wild poliovirus, it is everywhere the vaccine of choice for controlling outbreaks. It has been discovered, however, that the vaccine, on rare occasions, can mutate to become paralytogenic and spread from person to person, thus generating an outbreak. Experience to date indicates that such outbreaks may occur after months or even several years of silent spread. A second troubling discovery is the fact that, in certain individuals with a particular genetic defect, the virus may continue to proliferate in the intestinal tract for long periods without symptoms. One individual, who remained asymptomatic, was found to have excreted the virus for upwards of 10 years, excreting a strain which, when tested in monkeys, proved to be paralytogenic. Efforts to treat the infection with a variety of agents proved futile. Nineteen such chronic excretors have been identified but, because few have symptoms, it must be assumed that there are hundreds, perhaps thousands, of such persons who cannot be identified other than by chance isolation of poliovirus from the stool.

Despite these formidable problems, considerable progress has been made in the polio eradication effort. In 2003, the number of cases declined to 773, occurring in 14 countries.<sup>20</sup> However, only three countries appeared to be endemic (India, Pakistan, and Nigeria) by the end of the year. Most cases in the remaining countries represented importations or cases occurring earlier in the year. Both India and Pakistan appeared to be making good progress toward interrupting transmission, but a major setback occurred in Nigeria as a result of uncontrolled polio epidemics in northern Nigeria and subsequent spread of polio throughout Nigeria and to 12 other African countries. Repeated immunization days with

mass vaccination are being conducted in all affected areas, and hope is expressed that transmission might be interrupted in 2005. With three additional years being required to confirm that eradication has occurred, this would set the hoped-for year for confirmation of eradication at 2008, fully 8 years beyond the original target date. The cost of the program through 2003 exceeded \$3 billion, more than 30 times the cost of the entire smallpox eradication effort.

### Dracunculiasis

Prospects are brighter for the eradication of the parasite *Dracunculus medinensis*. An eradication program was agreed on in 1986 by the World Health Assembly with a target for achievement of 1995. Although the program is properly identified as a global eradication program, it involves eradication of the parasite only from generally remote rural areas of a number of tropical African countries as well as isolated areas of India and Pakistan. The strategy is directed toward preventing villagers from ingesting the minute freshwater crustaceans containing the larval parasites. Several methods are used: providing safe water supplies with new wells, destruction of the parasites in water by chemical means, and filtration or boiling of water before ingestion. Through surveys and reports, infected patients are detected, treated, and counseled not to enter the water and so contaminate it.

By 2003, the incidence of dracunculiasis had been reduced from an estimated 3.5 million cases (1986) to only 32,050 cases residing in 4679 villages in 12 countries of tropical Africa.<sup>21</sup> Two-thirds of the cases and infected villages were in Sudan, where continuing civil strife has handicapped operations.

### CRITERIA FOR ASSESSING CANDIDATE DISEASES FOR ERADICATION

Before embarking on still more eradication programs, it seems sensible to examine critically the feasibility of such efforts. Five principal determinants are proposed as minimum criteria to be met before an eradication program policy is decided.

1. *There is no natural reservoir for the organism other than humans.* Most infectious agents are *not* candidates for eradication because the responsible organism infects naturally both humans and other mammalian species or may survive naturally in the environment.
2. *The recovered patient ceases to harbor the organism and desirably is immune to later reinfection.* For those diseases in which the organism continues to be present in the body, either in its naturally infectious form or a latent one (e.g., hepatitis B, tuberculosis, varicella), there is little hope for eradication. An eradication effort in such instances would require an effort extending over a generation or more—hardly a feasible proposition given the difficulties in sustaining international commitments to programs for more than 10 to 20 years.
3. *The preventive intervention is affordable, effective, and logistically practicable to apply.* Affordability is critical given the fact that disease candidates for eradication afflict all or most of the poorest countries, where obtaining resources for vaccines that cost as little as

\$1.00 per dose have so far proved to be difficult. The feasibility of application reflects the realities of the limited transportation, health, and communications infrastructure in so much of the developing world. Vaccines or other treatments that require multiple contacts with the population are beyond local capacities in most developing countries. Thus, long-term treatment regimens, such as are needed in treating tuberculosis, all but preclude the possibility of eradication where such is the only feasible strategy.

4. *The disease is sufficiently important to warrant the effort.* Most countries considered smallpox to be a priority, and virtually all were engaged in control efforts when global eradication began. Thus, contributing resources to a global eradication effort was sound public policy for all countries and all did so. Many developing countries, however, required greater resources than they themselves could provide. International contributions were sought to bridge this gap.

Poliomyelitis eradication presents another type of challenge because the different countries have much more divergent degrees of interest in such an effort. The industrialized countries have generally accorded high priority to polio control. For the developing countries, however, a disease that produces paralysis in only 1 of 200 infected children, and results in death in only one-tenth of those, inevitably is of less concern than other diseases such as malaria and tuberculosis. Thus, in the polio eradication campaign, the expectation has been that the industrialized countries would provide virtually all funding for the conduct of the program worldwide and that developing countries would cooperate in implementing the program, but at little financial cost to themselves.

5. *Interruption of transmission has been demonstrated to be possible in developed countries and in some developing ones.* An eradication program is a costly investment whose benefits will not be realized unless eradication is achieved. Moreover, as has been apparent in almost every previous eradication program, expectations in terms of strategy, cost, and needed duration of effort have almost always proved to be seriously wrong when finally tested in the field. Accordingly, it would only be prudent to demonstrate empirically, first on a national and then on a regional scale, that the interruption of disease transmission is feasible before embarking on a hemisphere-wide or global effort.

Today, the feasibility of measles eradication is being tested in greatly intensified control programs throughout the Western Hemisphere.<sup>22</sup> Measles poses a special challenge because of the ease and rapidity of its spread and the fact that vaccination of children younger than 9 to 12 months old may be ineffective because of the interference of maternal antibody. Measles transmission has been interrupted for a several-year period in the Caribbean countries and for periods of months in the Americas. However, importations from endemic countries occur repeatedly and are difficult to identify quickly and to control before widespread outbreaks occur. Further experience is clearly needed before the practicability of measles eradication on a wider scale can be assessed.

## CONCLUSION

Given history and experience as background, what can be said for the future of eradication as a 21st-century strategy? In considering the prospects, it is necessary to bear in mind that there have been a number of costly eradication campaigns over the past century, but that only smallpox eradication has succeeded, and that by the narrowest of margins. And yet smallpox was by far the easiest of diseases to eradicate. Polio is probably the next most difficult challenge, but the differences in characteristics between the two diseases and the two programs are substantial and many challenges remain. Completing the polio eradication effort requires the continuing execution of vaccination and surveillance programs in the densely crowded Indian subcontinent and in large, all-but-inaccessible areas such as in Congo, Afghanistan, Somalia, and Sudan. Meanwhile, so long as the poliovirus continues to circulate, all other countries have little choice but to maintain their programs of vaccination and surveillance to prevent the virus from being reimported and becoming reestablished.

At this time, one must question the wisdom of even contemplating another eradication effort until the two eradication programs now in progress have been successfully concluded, until the lessons from those programs have been digested, and until the savings from polio eradication have begun to be realized.

Furthermore, there is at this time no candidate disease for which there is a sound scientific basis for eradication, for which the epidemiologic feasibility of doing so is clear, and for which there is a reasonable expectation of political commitment by both afflicted countries and those expected to provide the added resources.

## Vector Biology

JOSÉ M.C. RIBEIRO  
JESUS G. VALENZUELA

### INTRODUCTION

Many parasites, from viruses to nematodes, are transmitted to humans by arthropod vectors, usually by blood-feeding ticks and insects. As noted in several chapters of this book, these invertebrates are important in transmitting some of the most devastating human diseases. Because parts of the life cycle of such parasites are dependent on the life cycle of the vector itself, understanding of the epidemiology and transmission dynamics of these diseases necessarily includes understanding the factors affecting the life cycle of their vectors.

Ticks are specialized mites related to spiders and thus arachnids (having eight legs in the adult stage). Insects are hexapods. Because of the many similarities in their life cycle and transmission of pathogens to humans and other vertebrates, medical entomologists lump ticks and insects as arthropod vectors in medical entomology textbooks.

Although in a few cases pathogens are transmitted mechanically from one host to another by vectors in their attempt to feed, the general rule is for the pathogen to develop an intricate life cycle within the vector host. This life cycle may take from several days to months (as with some tick-borne pathogens). The time taken for the parasite to complete the life cycle within its vector is called the *extrinsic incubation period*. The *intrinsic incubation period* is the time in the vertebrate from infection to the first appearance of symptoms. Some pathogens develop exclusively within the digestive tract of the vector, such as *Trypanosoma cruzi* or *Leishmania* spp., whereas others develop within several compartments of the vector. Thus, *Plasmodium*, *Theileria*, and *Babesia*, as well as most arboviruses, will eventually locate themselves within the salivary glands of the vector, after crossing the gut, disseminating into the hemolymph, and finally invading the salivary glands. Filarial worms, depending on the species, develop in different organs of the vector (muscle, coelomic fat body, or malpighian tubules) and exit the vector by puncturing through its mouthparts while the vector attempts to feed.

### VECTOR LIFE CYCLE STRATEGIES

Most blood-sucking arthropods are oviparous, with the exception of some *Diptera* (including the tsetse), which are ovoviviparous (the egg hatches within the uterus and the larva feeds on secretions produced by milk glands). Two basically different growth strategies are observed: those having complete metamorphosis (*holometabolous*; Fig. 8-1) and those having incomplete metamorphosis (*hemimetabolous*; Fig. 8-2).

Holometabolous insects follow the model of the butterfly, the caterpillar being very different from the adult animal. Hemimetabolous development follows the cockroach model, the immature animal being similar to the adult. In all cases, the immature animal feeds after coming out of the egg, and molts to a larger stage, shedding its old cuticle in a process called *ecdysis*. The newly emerged insect has a soft cuticle, ingests air or water, and enlarges itself before the cuticle hardens again. This feeding and molting process occurs from two to five times before the arthropod molts to an adult. Before molting to the adult, the general appearance of the insect or tick is similar (only larger) to the newly hatched animal. The last molt in hemimetabolous animals transforms the arthropod into an adult having sexually mature reproductive organs and fully developed wings (in species having wings, they are found only in the adult stage). Also, the adult cuticle is generally different from the immature cuticle. In holometabolous insects (all ticks are hemimetabolous), the last immature molt leads to a pupa, where metamorphosis to the adult stage occurs. All immature stages of holometabolous insects are called *larvae*, whereas all immature stages of hemimetabolous insects are called *nymphs*. In hard ticks (Ixodidae), there are two immature stages: the first is a larva and the second is a nymph.

Nymphs and adults of hemimetabolous insects and ticks thus have the same general appearance (varying in size), usually sharing the same habitat and feeding on the same types of food. However, larvae and adults of holometabolous insects are very different morphologically, have different habitats, and have different feeding habits. Immature and adult ticks, as well as nymphs and adult kissing bugs (triatomids) and bedbugs, all feed solely on blood, while larvae and adults of mosquitoes and sandflies feed on very different things, with only the adult female insect feeding on blood. Thus control of holometabolous insects involves two completely different strategies: those aimed at the immature and those aimed at the adult stages of the vector.

### LIFE SPAN, REPRODUCTIVE CAPACITY, AND VECTOR ABUNDANCE

Insects and ticks also vary greatly in their life span and reproductive capacity. Mosquitoes, for example, can complete a life cycle within 1 to 2 weeks, while some ticks may take several years and even more than a decade if food is scarce. Additionally, a single female may produce only a few offspring (such as the tsetse), several hundred (mosquitoes), or thousands (ixodid ticks). Of course, most offspring of such insects never become adults, as only one female needs to achieve maturity to replace the preceding one and keep the vector population size constant. However, changes in the environment that make possible a larger number of larvae and nymphs to become adults can create explosive increases in vector abundance, and thus create epidemic conditions. In the case of mosquitoes, an unusually good rainy season may produce several generations resulting in a large number of adults. Ticks, with their longer life cycles, have populations that can fluctuate on a yearly basis, as can be the case with winter weather fluctuations in New England affecting the density of the deer tick, the vector of Lyme disease. Vector abundance normally exhibits a large variance both temporally and spatially, and this is reflected in the time and spatial dynamics of vector-borne diseases.

**FIGURE 8-1** Life history of a holometabolous insect, represented by the life cycle of a black fly, *Simulium damnosum*. Note the very different aspects of immature and adult insects that share different habitats. (Modified from Beaty BJ, Marquardt WC: The Biology of Disease Vectors. Fort Collins, University Press of Colorado, 1996.)

**FIGURE 8-2** Life history of a hemimetabolous insect, represented by the life cycle of a triatomine bug, *Rhodnius prolixus*. Note the similar appearance of all instars, which also share the same source of food. (Modified from Beaty BJ, Marquardt WC: The Biology of Disease Vectors. Fort Collins, University Press of Colorado, 1996.)

The life span of a vector relative to the time taken for the parasite to complete its invertebrate life cycle is also very important for understanding the dynamics of vector-borne diseases. For example, most malaria parasites take at least one week to complete their life cycle in the adult female mosquito, but most mosquitoes die of old age before this amount of time. Thus, the longevity of the adult female mosquito is a very important variable determining how many secondary cases a single case of malaria can generate given a certain number of mosquitoes available per person. On the other hand, ticks can outlive most of their rodent hosts, and this can be very important in the perpetuation of viral diseases of short duration (e.g., diseases that either kill the host or to which the host becomes immune) in a small-sized rodent population.

## HOST SPECIFICITY

There are two basic strategies followed by those animals that feed on vertebrate blood: a hunting strategy, where the insect actively searches for its prey (most blood-sucking arthropods are micropredators, not parasites), and an ambush strategy, where the insect or tick positions itself to maximize contact with its host or prey. The tsetse, horse fly, and mosquito are good hunters, whereas most ticks and fleas maximize ambush.

The limited size of the brain of invertebrate animals cannot deal with too much information and accordingly they select a group of very distinct variables to make a decision to attack what they think is a host. Visual cues, temperature gradients (including infrared “vision”), and olfaction will mediate host location. For example, some tsetse species are attracted by anything larger than a dog that moves at a certain speed (including a car), are even more attracted if the object smells like cattle urine, and are really excited over a warm surface. Carbon dioxide and water vapor are common attractants to many ticks and hematophagous insects. Recently, the smell of human feet (made possible by the same genus of bacteria that ferments Limburger cheese) was shown to be attractive to *Anopheles gambiae*, a highly anthropophilic (high specificity for feeding on humans) mosquito.

Hematophagous arthropods may become very host-specific or very catholic in their feeding habits depending on the location they choose to start their foraging as well as the cues that each species selects to identify a host. Host specificity is a very important concept for understanding the dynamics of vector-borne diseases, as they have a squared value in the equations of transmission dynamics. For example, a mosquito needs to feed once on a person with malaria to acquire the *Plasmodium* parasite and feed again on another person several days later to deliver the parasite. If only 50% of the population of a particular mosquito species would feed on humans, and only 50% of the mosquitoes feeding on the sick person acquire gametocytes (the parasite stage infectious for the mosquito), then only 50% of this 50%, or only 25% of the entire population, would then transmit the parasite to humans. *An. gambiae* mosquitoes feed almost exclusively on humans (greater than 98%), even when other sources of blood (e.g., cattle) are available, and this is one of the reasons this mosquito is such a good malaria vector. On the other hand, some vectors are relatively nonspecific, and they may become good bridge vectors for transferring zoonotic pathogens, such as *Ixodes scapularis* vectoring *Borrelia burgdorferi* from the white-footed mouse to humans.

## VECTOR COMPETENCE

Vector-borne parasites can be very selective in the host species in which they complete development. For example, human malaria can be transmitted only by mosquitoes of the genus *Anopheles*. But there are anopheline mosquito species that serve very poorly or not at all in the invertebrate *Plasmodium* life cycle. This may be due to many biologic reasons varying from the time the mosquito peritrophic matrix is formed (a chitinous dialysis membrane-like structure that forms around the blood meal inside the mosquito gut that may serve as a barrier to the invading parasites), to the mosquito's ability to mount a melanotic reaction to the developing oocyst, and to the sporozoite's ability to find the mosquito salivary gland and survive the mosquito's hemolymph defense system. Other mosquitoes can develop heavy sporozoite infections of the salivary glands, even when feeding on lightly parasitemic hosts. This biologic ability of a vector to serve (or not) in the parasite's life cycle to its infective stage is called *vector competence*. It is actually expressed as the fraction of a particular vector population or species that can transmit the parasite after taking an infectious blood meal. In many cases the term *vector potential* is used synonymously with vector competence, mainly in a context where a potential vector species from a certain geographic area is being investigated for its ability to carry a parasite from another geographic area. For example, a medical entomologist from California may check whether local *Culex* mosquitoes are able to complete the life cycle of a virus found in Japan. The results of such tests of vector competence may indicate the potential for that particular Japanese viral disease to appear in California.

## VECTORIAL CAPACITY

Even when determining that a particular arthropod species is competent for the parasite to complete its life cycle, this does not mean that such a vector will be important in maintaining disease transmission in the real world. For example, in the laboratory one may force a mosquito or tick to take a meal from a host it will never find or prefer to feed on in their habitat. Or the life span of the vector may be so short, compared to the extrinsic incubation period, that most of the vectors are dead before transmission occurs. Or the abundance of the vector may be so low that it will not sustain transmission of the pathogen in real-life conditions. To understand the role of a particular vector in the transmission of a particular pathogen, the concept of *vectorial capacity* was developed. Vectorial capacity includes not only the concepts of vector competence but also those of vector abundance, host specificity, vector longevity, and the time taken for the parasite to develop its life cycle within the vector (extrinsic incubation period). Vectorial capacity has a precise numerical meaning that represents the number of infective bites generated by a single case of a particular vector-borne disease, on a per day basis. This concept was developed by workers in the field of malariology and may be adapted to understand several other vector-borne diseases where vector survival is on the same order of magnitude as the extrinsic incubation period (this includes most mosquito-, sandfly-, black fly-, and flea-borne diseases).

In formal numerical terms the vectorial capacity equation can be expressed as:

$$VC = m \cdot a^2 \cdot b \cdot \{p^n / -\ln p\}$$

where VC is vectorial capacity (number of mosquito infective bites generated by a single parasitemic patient);  $m$  is number of mosquitoes available per person;  $a$  is human biting rate;  $b$  is vector competence;  $p$  is probability of the vector surviving one day; and  $n$  is extrinsic incubation period.

This equation can be understood in a very straightforward way by following each term and its relationship to the transmission dynamics of the parasite in the invertebrate host. It is obvious that the number of secondary disease cases of a mosquito-borne disease would be proportional to the number of vectors available per person (Fig. 8-3), that is, the more mosquitoes, the more chance of one case generating another case of malaria. The number of mosquitoes, however, has to be qualified regarding their host specificity, as described previously. If only 10% of the mosquitoes feed on a person, only a maximum of 1% could potentially deliver the parasite back to human hosts, because in order to transmit the disease they would have to feed again on people, assuming that on the second blood feeding the mosquitoes have the same chance of feeding on either a human host or another host (this is a nontested assumption of the MacDonald model!). Vectorial competence would further interfere with the ultimate number of infective bites, as not all vectors may develop the parasite to its infective stage (and that was why “a maximum of 1%” was written in the preceding discussion). The term  $p^n$  expresses the number of mosquitoes surviving the length of time associated with the extrinsic incubation period. When collected from the wild, mosquito mortality follows roughly an exponential decay curve,

**FIGURE 8-3** Graphical representation of two different sets of equal numbers of mosquitoes (100) biting a person infected with malaria at day 0. One set has a daily survival rate of 0.95 whereas the other set has a rate of 0.855. The human biting rate and vector competence are equal to 1 in both mosquito sets. Note that the two sets of mosquitoes die at different rates and continue to bite people without transmitting disease until  $n$  (extrinsic incubation period) days have elapsed. After this time interval, mosquitoes have infected salivary glands and surviving insects will produce infective bites. The total number of infective bites will be proportional to the number of mosquitoes surviving  $n$  days multiplied by their life expectancy in days. The result is equal to the vectorial capacity (VC) and is numerically equal to the marked areas under the curve. Note that a 10% change in the survival rate leads to a ninefold change in the vectorial capacity.

and thus the number of mosquitoes surviving  $n$  days would be exactly  $p^n$ . For example, if a mosquito has a 90% probability of surviving one day, then the number of mosquitoes that would survive 10 days would be  $0.9^{10}$  or 34.9% of the initial mosquito population (see Fig. 8-3). Thus, at the end of the extrinsic incubation period, only a fraction of the vectors would be delivering the pathogen. However, even considering the number of mosquitoes that survive  $n$  days, these mosquitoes would not survive forever, and would continue to die. Because most infected mosquitoes do not have their mortality rate changed due to infection with the parasite, we can assume that the daily survival rate of such mosquitoes is still  $p$ . To calculate the number of infective bites delivered for the remainder of the life of the mosquitoes, one would have to integrate the area under the survival curve for those mosquitoes. We know from calculus that to calculate the area under an exponential with a rate  $p$ , the solution is  $1/-\ln p$ . Thus the area under the mosquito survivorship curve from day  $n$  (the extrinsic incubation period) until all mosquitoes are dead represents the vectorial capacity of a particular vector-pathogen association.

The preceding considerations are helpful in understanding the interrelationships of the several variables affecting the transmission dynamics of many vector-borne diseases. For example, it becomes clear that the main parameter affecting vectorial capacity is the term  $p^n$ , which has an exponential value. Some of the best mosquito vectors are long-lived when compared with other species. The human biting rate is a quadratic term, whereas mosquito abundance  $m$  and vector competence  $b$  are linear terms. Indeed, many poorly anthropophilic vectors such as *Anopheles albimanus* or *Anopheles culicifascies* will only transmit human malaria when they are extremely abundant (and thus the  $m$  term compensates for the lack of value on  $a^2$ ). Similarly, *Aedes aegypti* is a poor vector for urban yellow fever in Nigeria (the virus strain was of sylvatic origin), having poor vectorial competence  $b$ , but when conditions favor extremely abundant mosquito numbers, epidemics have occurred.<sup>1</sup>

The parameters of the previous equation are an extreme simplification of what occurs in real life, but useful insights are obtained even when appreciating its limitations. Many of the terms are considered constants, but in real life they may be functions of other parameters. For example, the extrinsic incubation period changes with temperature; this is an important variable with most malarial and viral pathogens. Increased temperature may reduce incubation time significantly, increasing the vectorial capacity in larger proportion due to the exponential behavior of  $p^n$ . Similarly, increased humidity may significantly increase daily survival of mosquitoes (that otherwise may easily die of dehydration), also affecting vectorial capacity in an exponential fashion. The human biting rate of a particular vector species may also change with the repertoire of hosts in a given location. For example, many mosquitoes prefer cattle or horses for a blood meal, but when “progress” arrives and horses and cattle disappear, the same species may start to bite humans preferentially and create a condition for human disease transmission.<sup>2</sup>

## BASIC REPRODUCTIVE RATE

To convert the vectorial capacity equation into the basic reproductive rate ( $R_0$ ) of the particular disease, one has to

include the terms that represent the life cycle of the parasite in the human host. These are represented by the number of days that the infection lasts in the vertebrate host, expressed by the disease recovery rate  $r$  (measured as the probability per day to revert to the nonparasitemic state), and by the probability  $c$  that the new secondary host will acquire the infection once bitten by the vector. We thus have

$$R_0 = VC \cdot c/r$$

It is interesting to note the regulatory effect of vertebrate host immunity on  $R_0$ . The more time that a person stays sick (and thus the smaller the recovery rate  $r$ ), the more mosquitoes are infected and the larger the disease  $R_0$ . However, in hyperendemic situations people acquire some immunity and the recovery rate is much faster (larger); also, the chance of getting infected by an infective bite ( $c$ ) is smaller due to immunity. Both terms thus conspire to bring down  $R_0$  in hyperendemic conditions. Conversely, this is why it is difficult to accomplish sustained control of malaria in hyperendemic conditions: as herd immunity goes down, the disease reproductive rate fights back. In the process of controlling the disease (and thereby reducing immunity), the scenario may change from one of “calm” or “quiet” endemicity to one of severe epidemics.

## VECTOR LONGEVITY

The preceding equations are useful for understanding the dynamics of vector-borne diseases when the vector is relatively short-lived with reference to the extrinsic incubation period of the particular pathogen. Other scenarios for transmission can happen where vector longevity, for example, is not an important issue. Ticks are often more long-lived than their vertebrate hosts, as is the case of most rodents. As seen in Chapter 3, population size is an important determinant of the perpetuation of many infectious diseases that leads to lifelong immunity. For example, it is postulated that a human population settlement of at least 200,000 people is necessary to produce enough nonimmune children to sustain measles. One can, however, envision a small population of rodents (fewer than 1000) and their ticks to sustain a virus that produces lifelong immunity by the “ping-pong” effect of the virus being shuttled from the vertebrate to invertebrate hosts on an annual basis. For example, let us imagine a rodent population in sub-Saharan Africa that typically breeds in the annual rainy season, and their ticks, which also feed on an annual cycle. During the rainy season, both larvae and nymphs feed on the rodents simultaneously for a period overlapping two months. Infected nymphs can transmit the virus to nonimmune rodents, and a few days later these rodents transmit the pathogen to larvae, which will feed again only in the next year (after molting to nymphs), when young, nonimmune rodents are available. A disease of short duration, without relapses, conferring lifelong immunity can thus perpetuate itself even within a host population of small size. The same reasoning applies in the absence of vectors if the pathogen can live long enough in the environment to reinfect young mice, as is the case with the North American hantavirus. Because rodents have a relatively short life span, they need a relatively small population size to keep diseases in an enzootic state for a pathogen. On the other hand, rodents can achieve very large population sizes, which makes the situation still worse.

This may be one of the explanations for the continuous emergence of pathogens associated with rodent hosts; that is, rapidly generating rodents can maintain cycles of pathogens even when they induce lifelong immunity.

## TRANSOVARIAL TRANSMISSION

Some vector-borne pathogens can be transovarially transmitted from the adult female to its offspring. Some mosquitoes can have a small or substantial portion of their eggs containing viruses that will continue their development in the mosquito larvae up to the adult stage. In this case, the first bite of the adult female may inoculate the pathogen into the vertebrate host. Transovarial transmission is often referred to as *vertical* transmission of a pathogen, to differentiate it from *horizontal* transmission, when one vector acquires a pathogen from a vertebrate host. *Sexual* transmission of mosquito-borne viruses was also demonstrated in some rare cases, where male (non-blood feeding) mosquitoes that were infected by the transovarial route could transfer the virus to females via copulation; this also occurs with African swine fever virus in argasid ticks.

In some cases, transovarial transmission of a pathogen is an essential feature of the pathogen life cycle. For example, bovine babesiosis (*Babesia bovis*) is transmitted by the cattle tick (*Boophilus microplus*), which is a single-host tick. *Boophilus* larvae attach to a host, staying with the same animal for life, until the adult female tick takes a large blood meal, drops off, lays thousands of eggs, and dies. There is no way of continuation of the *Babesia* life cycle without transovarial transmission of the protozoa from female to young larvae.

Transovarial transmission may be an important route for the perpetuation of other pathogens that are also transmitted horizontally. For example, a mosquito-borne virus causing epizootics or epidemics might lead to increased herd immunity of the vertebrate hosts that prevents further spread of the virus within the vertebrate population. The virus could perpetuate in nature during the interepidemic period by vertical transmission, until the herd immunity decreases again and a new invasion of the vertebrate population by the pathogen can occur. Even if vertical transmission is relatively inefficient (e.g., if only 10% or less of the offspring become infective), the large number of horizontally infected vectors during epidemic times could lead to a few vertically infected individuals after several mosquito generations, enough to initiate a new epidemic. This is again a case of the ping-pong transmission described previously for tick-borne pathogen scenarios, but due to the much shorter life of mosquitoes, vertical transmission allows for the pathogen to hide within vectors until vertebrate herd immunity goes down.

## MODES OF VECTOR-BORNE DISEASE TRANSMISSION

In most cases vectors are not born with parasites they transmit, but rather they get infected while feeding on blood. Once reaching the vector's gut, parasites either continue to live there, such as *Leishmania* and *Trypanosoma*, or they cross the insect midgut epithelium into their vector's hemocoel, an open cavity between the digestive system and the cuticle, filled by hemolymph, the insect's blood, and other insect organs.

Once in the hemolymph, parasites such as *Plasmodium* and several arboviruses will infect their vectors' salivary glands. When vectors salivate into their hosts' skin in their attempt to obtain a blood meal, parasites are thus inoculated. Mosquito-borne parasitic worms can develop in the thoracic muscles, fat body, or Malpighian tubules of their vectors, where they develop to the infectious stage 3 larvae, when they leave the nursing organ back into the hemolymph. These worms are too big to invade the salivary glands, but while the vector is feeding, triggered by the sudden temperature increase, they puncture the vector cuticle actively moving into the vertebrate skin where they attempt to penetrate the tissue through the feeding wound. In many cases the worms just dehydrate before they can achieve their goal, and this is one of the reasons filarial transmissions such as *Wuchereria* are only found in humid places. Gut-dwelling parasites can be transmitted either when they are regurgitated into the vertebrate host, such as *Leishmania* and flea-borne plague, or they can be delivered in the vector feces, such as happens with American trypanosomes. Defecation while feeding is relatively common with vectors because of the relatively huge blood meal, which compresses the insect rectum, and also because of the very rapid water transport from the midgut to the hemolymph and from there to the rectum via the Malpighian tubules, the kidney equivalent in arthropods. Interestingly, desert-dwelling triatomines are not good vectors, because they conserve water so well that they end up not defecating on their hosts. However, rodent reservoirs may acquire the disease while eating the triatomines.

### Role of Vector Saliva in Parasite Transmission

Most vector-borne parasites invade their vertebrate hosts in sites where the vector has injected saliva. In the case of salivary-borne pathogens such as malaria, it is important to stress that sporozoites are not delivered into the vertebrate host circulation, as most diagrams show, but rather are released inside the host skin, from where they actively move into the blood circulation. When mosquitoes reach a blood vessel, they suck the blood so fast that all sporozoites end up in the mosquito gut and are lost. *Leishmania* organisms, although not delivered via vector saliva, are delivered in the same wound where salivation occurs, thus the inoculation is coincident with a site exposed to their vector's saliva. Blood feeders' saliva contains an array of pharmacologically active components that assists them to obtain a blood meal. This salivary cocktail includes potent anticoagulants, anti-platelet molecules, vasodilators, and immunomodulators, allowing blood feeders to disarm the vertebrate's hemostatic and inflammatory system to their advantage. This pharmacologically modulated site may become a better location for pathogen establishment; in fact, *Leishmania major* parasites when co-injected into mice with sandfly saliva result in greater infection as compared to inoculation with parasites alone. The same phenomenon has been observed in transmission of viruses by ticks and mosquitoes.

Vertebrate immune responses generated to the bites of arthropod vectors can influence vector feeding and/or the efficiency of pathogen transmission. In the case of ticks, repeated feeding on non-natural hosts results in immune responses that lead to tick rejection. However, immune-mediated tick

rejection does not occur, or is milder, when ticks feed on natural hosts. On the other hand, in the case of *Phlebotomus* sandflies, repeated feeding in mice results in delayed type hypersensitivity that causes sandflies to probe and feed faster in these animals. These immune responses, however, have a deleterious effect on some pathogens transmitted by vectors. Immune responses to *Ixodes scapularis* in natural and non-natural hosts result in protection against *Borrelia burgdorferi* infection. Similarly, immune responses to sandflies result in protection against *Leishmania major* infection, and a strong correlation exists between individuals generating immune responses to the sandfly *Lutzomyia longipalpis* and being protected against *Leishmania chagasi* infection. Therefore, in some vector-borne diseases, previous exposure to vector saliva may result in immune responses capable of preventing parasite transmission. It should be emphasized that probably not all immune responses to vector bites are protective against all vector-borne pathogens, as not all individuals respond identically to insect bites. The outcome probably depends on the biology of the pathogen in its vertebrate host. In the case of human malaria, for example, sporozoites tend to leave the bite site within minutes in their journey to the hepatocyte, and thus are not exposed for very long to immune effects of a sensitized skin. However, presentation of circumsporozoite antigen, which remains in the sporozoite trails, will occur in the context of antisaliva immunity. Therefore, the role of saliva in parasite transmission seems to be a two-edged sword phenomenon. In one case, salivary secretions favor the establishment of the pathogen or parasite in vertebrate hosts not previously exposed to salivary components. This enhancement effect may be due to the potent bioactive, anti-inflammatory and immunosuppressive properties of vector's saliva. On the other hand, salivary secretions may decrease transmission of pathogens and parasites in a vertebrate host previously exposed to vector salivary components. This outcome may be due to neutralization of the salivary bioactive components or to indirect killing of the pathogen by cellular immune responses to salivary proteins. Vector salivary secretions are therefore an important component in the transmission of pathogens or parasites and for this reason are being targeted as an alternative approach to control vector-borne diseases.

### VECTOR IDIOSYNCRASIES

The following sections are summaries of the life cycle aspects of the most important vectors.

The order Diptera includes all flies, those insects containing only one pair of wings in the adult stage, and a pair of halteres, which are atrophied wings. They are all holometabolous, usually having four larval stages or instars, one instar of a nonfeeding pupa, and finally the adult male and female. In some species of mosquitoes and many sandflies, larvae can withstand prolonged periods without food in diapause during the dry or cold season.

#### Mosquitoes

All larval instar stages of mosquitoes are aquatic. *Aedes* eggs are laid singly at the edge of the water; these embryonate and remain dormant until they are covered by water again.

*Culex* eggs are laid together in a raft on the surface of the water, while *Anopheles* eggs are laid singly on the water surface or on mud, hatching in both situations after a few days. The female mosquito, depending on the species, may choose either small containers or large bodies of water to lay her eggs. Also, the quality of the water chosen for oviposition will vary with the mosquito species. Usually *Aedes* and *Anopheles* mosquitoes will choose relatively clear water, as the larvae do not withstand much suspended organic matter or scum, whereas *Culex* mosquitoes will thrive in such environments. Thus urban *Culex pipiens* will develop in great numbers in pit latrines, while *Aedes (Stegomyia)* spp. may thrive in small containers containing drinking or rain water. Developmental time from egg to adult may take from 5 days to 3 weeks, depending on the species, temperature, and larval food supply. Only the adult female mosquito feeds on blood, which is used for egg development; usually more than 100 eggs are produced per blood meal. Both male and female mosquitoes take sugar-rich meals, which energize flight. Mosquitoes are vectors of many arboviral diseases such as dengue and yellow fever (transmitted by *Aedes* mosquitoes), malaria (only anopheline mosquitoes transmit human malaria), bancroftian filariasis (mainly by *Culex*, but also *Anopheles* mosquitoes), and brugian filariasis (*Aedes*).

### Sandflies

These insects belong to the family Psychodidae, which also contain the sewer flies. Sandflies are vectors of arboviral, bacterial (*Bartonella*), and protozoal (*Leishmania*) human diseases. Immature sandflies are terrestrial, the larvae usually inhabiting mature, organically rich soil that has a composition similar to potting soil. Most vectors belong either to the New World genus *Lutzomyia* or to the Old World genus *Phlebotomus*. They may live within human dwellings, but are more commonly associated with peridomestic organic trash, rodent or other vertebrate nests, or forest soil. The immature life cycle of many important vector species is not known precisely. The time from egg to adult can be 45 days or longer depending on temperature. Some species have only one cycle per year, the third instar being the overwintering stage. Only adult female flies feed on blood, and both adults also feed on sugary solutions produced by aphids, fruits, or flower nectar. Adults do not fly well and show a typically “hopping” flight, close to the wall or another surface.

### Black Flies

Black fly larvae are all aquatic and need moving water to feed. Most species attach to a substrate within a fast-moving plume of water, where they open their feeding fans to catch nutrients in the form of particulate organic matter. *Simulium neavei* is an important vector of onchocerciasis in central Africa and occurs in lakes where it is attached to the gills of crabs. The flow of water on the gills is sufficient for oxygen exchange in an otherwise calm body of water. Developmental time from egg to adult varies with temperature and species from 2 to nearly 4 months. Adults are good fliers and may disperse with the wind for many miles from their breeding site. Similarly to mosquitoes and sandflies, only the adult female feeds on blood.

### Horse Flies and Deer Flies (Tabanids)

These large flies are vectors of *Loa loa* filariasis in West Africa and can also mechanically transmit equine infectious anemia virus between horses. Whether they can also transmit other viruses by mechanical transmission is yet unknown. Carnivorous larvae emerge from eggs deposited in moist grass and soil, where they feed on other insects, such as grubs. Male horse flies feed on vegetable material and do not bite. Females feed by making relatively large and painful cuts in the skin. The flies feed from the hematomas that accumulate in such lesions. They are usually not very efficient feeders, feeding several times per day, often flying directly from one host to another.

### Tsetse

The tsetse (the word *tsetse* means fly destructive to cattle; thus the name tsetse fly is redundant) is an ovoviviparous vector of African trypanosomiasis. The female fly has a uterus wherein an individual egg hatches, the resulting larva feeding on secretions provided by milk glands. About every 10 to 15 days, the female fly deposits a large third instar, a larva that burrows into the ground and immediately pupates giving rise later (3 to 4 weeks, or longer) to another adult fly. Both male and female flies feed exclusively on blood. An adult female fly can at most produce six to eight such offspring, half of which are males. Tsetse flies have low reproductive capacity, and their population can be relatively easily controlled by trapping adult flies with ox urine-baited traps. Indeed, capture of 75% of the adult population can reduce the  $R_0$  of the fly population to lower than unity and thus to local extinction. An equivalent effort for mosquitoes would require trapping of more than 95% of the adult population because of their larger reproductive capacity. Different species of tsetse have different host specificities (from crocodiles to wart hogs and humans), as well as different habitat requirements (dry savanna or riverine environments). Accordingly, each particular African trypanosomiasis scenario will be linked to the particularities of the bionomics and life cycle of the particular trypanosome vector.

### Fleas (Siphonaptera)

These holometabolous organisms are always associated with the nest of their hosts, and thus a close relationship usually exists between a flea species and its host. This may explain why there are about 200 genera of fleas, while all remaining blood-sucking arthropods make up another 240 genera. Fleas are vectors of rickettsial (murine typhus) and bacterial (plague) pathogens. Also, fleas infected with *Yersinia pestis* develop a “blocked” gut, causing the flea to move from host to host and spread the bacterial pathogen. When the flea’s natural zoonotic hosts start to die from disease, the hungry fleas may attack other host species, bridging the pathogen from an epizootic or enzootic to an epidemic cycle. Similarly, fleas that are left in empty burrows may attack anything that looks like food after a period of starvation. Both male and female fleas feed exclusively on blood. Females lay their eggs in the host’s nest, the larvae feeding on a mix of organic material comprised of skin keratin mixed with dried host blood that is squirted from the anus of the adult flea while it feeds.

Thus small blood spots found in the bed linen of humans are an indication of flea-feeding activity.

### Lice (Anoplura)

These are wingless hemimetabolous insects that live their entire lives associated either with human hair (*Pediculus humanus capitata*) or with the human body, where they stay attached to human clothes (*Pediculus humanus corporis*). When laid, eggs are attached to hairs or clothes. All instars feed exclusively on blood. The insects are sensitive to a decrease in temperature, so the body variety will survive only in conditions where clothes cannot be washed and changed regularly, as is the case following social turmoil and in homeless populations. Only *P. humanus corporis* is incriminated as a vector of louse-borne typhus and louse-borne relapsing fever. The insecticide DDT was actually discovered in World War II in a program to discover novel pediculicides. The Allies were anticipating huge mortality from louse-borne typhus after the invasion of Italy.

### Kissing Bugs (Hemiptera)

Hemiptera is the insect order with the common name of bugs (as flies represent the Diptera). The family Reduviidae has predacious, plant-feeding, and blood-feeding insects. All are hemimetabolous developing through five nymphal instars. The subfamily Triatominae comprises about 125 species in 15 genera, all having exclusively blood-feeding habits. Nymphs and adults live associated with nests, burrows, or habitations of their hosts. Kissing bugs can be very selective for their hosts; some are associated exclusively with birds, others with bats, and so on. Kissing bugs are vectors of *Trypanosoma cruzi*, the causative agent of Chagas' disease. This disease has a zoonotic cycle, as well as an endemic cycle. Thus, vectors maintaining the zoonotic cycle are associated with wildlife or domesticated animals, and vectors associated with human disease are found in the domestic environment. Other species may be found within the peridomestic environment, particularly in chicken pens, stables, woodpiles that harbor rodents, and so forth. Some species of the genera *Triatoma*, *Panstrongylus*, and *Rhodnius* are highly adapted to the human environment. Nymphs and adults take large meals of blood (5 to 10 times their own weight) in 10 to 30 minutes. They usually attack their victims while the host is sleeping, biting in the face, thus the name kissing bug, or *barbeiros* (barbers) in Portuguese, or *vinchuca* or *chinha* in Spanish. The large meal triggers a diuresis in the bugs, which then defecate while still feeding, depositing *T. cruzi* on its vertebrate host. The life cycle from egg to adult may take from less than 6 months to 2 years depending on the species. Some species (such as most *Rhodnius* spp.) may take only one meal to accumulate all the food they need to molt to the next instar. Others may take two or more meals per instar. *Rhodnius* may go from egg to adult in 6 months, having only 5 meals of blood, each blood meal taking less than 15 minutes. In 6 months of life *Rhodnius* feeds for a total of around 60 minutes before it molts to an adult. During the remaining time the bug is digesting its meal and hiding from predators. Adult females copulate once and are fertilized for life, laying their eggs in the same places in which they hide. Both male and females feed on blood, and may do so several

times during adult life. Females lay about 30 eggs per blood meal. With so much time vulnerable to predators, hiding places are very important for kissing bugs. Most domestic species are associated with poor housing construction (mud and stick) that creates small holes and cracks in the walls (most *Triatoma* and *Panstrongylus*), or with dirt floors (*Triatoma dimidiata*), or with thatched roofs (most *Rhodnius*). Accordingly, endemic Chagas' disease is highly correlated with poverty in rural areas of Central and South America.

Control of kissing bugs is relatively simple compared to that of other vector-borne diseases, and great progress has been made in the last 30 years in reducing domestic Chagas' disease transmission in South America. As zoonotic cycles continue to exist, Chagas' disease may disappear for a time in some areas only to reemerge later as favorable conditions reappear and a bridge from the sylvatic to the human disease cycle takes place. Accordingly, research emphasis on bugs is shifting from domestic species to those that are peridomestic and may serve as bridge vectors.

### Ticks (Acari)

For medical entomologic purposes, we can consider ticks as coming in two varieties: hard (family Ixodidae) and soft (family Argasidae). All feed exclusively on blood, but can also produce hygroscopic saliva that captures moisture from the air. Thus these arthropods can survive long periods of time without desiccating. Indeed, some soft ticks can withstand years without a blood meal and without dehydrating. There is, however, a limit to the degree of air humidity at which the saliva can draw water from the atmosphere and this in great part limits the range of different tick species, both on a macro- and a microgeographic area.

#### Hard Ticks (Ixodidae)

Hard ticks have two immature stages, a six-legged larval stage and an eight-legged nymphal stage; the adults also have eight legs. Ticks are vectors of many arboviral, rickettsial, bacterial, protozoal, and even filarial organisms (the last not of human importance). Ticks can take huge meals compared to their size and stay attached to feed on their hosts for several days to weeks. Adult females take a single blood meal, drop off the host, and produce many hundreds to thousands of eggs before dying. Typically, larval ticks take microliter or sub-microliter meals, nymphs will take several microliters, and an adult will take hundreds of microliters to over 1 mL of blood. Thus a mouse can serve well as a host to immature ticks, but a few adult ticks would exsanguinate the animal. Hard ticks can be classified as being one-, two-, or three-host species. For example, the cattle tick *B. microplus* is a one-host tick. Thus larvae coming from eggs deposited in the field ambush a cow and stay with the same animal for life. Two-host ticks will attach to a host as a larva, continue with the host after the nymphal molt, and detach from the vertebrate after the nymphal meal. They molt to adults in the environment and then quest for another host. This strategy allows the tick to use one set of hosts (usually smaller animals) for the immature stages, and another set (usually larger animals) for the adult stages. Many three-host tick species will feed on birds or rodents in their immature stages and on deer or other larger mammals as adults.

There are also three-host species associated with small vertebrates, but in this case the adult female takes smaller meals and lays a smaller number of eggs. Note that transmission of pathogens is potentially greater in three-host tick species, and that transovarial transmission is an important component to be considered.

Depending on the tick species, seasonality of the three life stages is also an important consideration for the transmission dynamics of tick-borne diseases. Seasonality may depend not only on temperature but also on weather cycles in which moisture levels fluctuate. If immature ticks feed on the same hosts at the same time, pathogens might be transmitted from nymphs to larvae. Sometimes larvae and nymphs may feed on the same type of hosts, but several months apart (a good tick strategy to prevent overburdening the food supply). In this case transmission of pathogens from nymphs to larvae would require a chronic infection of the vertebrate host, as is the case with Lyme disease (see the ping-pong effect discussed previously). Tick life cycles take typically less than a year to 2 years and may sustain the parasite in nature while herd immunity of short-lived mammals wanes.

### Soft Ticks (Argasidae)

Soft ticks have a variable number of immature stages or instars depending on the species and availability of blood. Unlike hard ticks, which stay attached to their hosts for several days, soft ticks usually take meals lasting from a few minutes to one hour. Some tick species, such as *Ornithodoros coriaceus*, may produce in their hosts large and painful hematomas. Soft ticks are usually associated with nests or burrows of their hosts, or the places where host animals rest. They are vectors of arboviral and bacterial diseases, such as relapsing fever borreliosis.

### Trombiculid Mites

These mites are not ticks, but, like ticks, are also acari. They can transmit rickettsial pathogens, such as *Orientia tsutsugamushi* (scrub typhus). Only the six-legged larvae of these mites feed on tissue fluid, nymphs and adults being predacious on other arthropods. Transovarial transmission of the pathogen is thus required for maintenance of disease foci.

## VECTOR CONTROL

One can either kill vectors, or avoid their contact by various means, to prevent vector-borne diseases. Note that holometabolous insects have at least two different strategies for their control. One can perform larvicide or adulticide. Insecticides or other control agents will have to be delivered to different sites in the case of most holometabolous insects, depending on whether larvae or adults are being controlled. Malaria control is an example of holometabolous insect control. Malaria is transmitted by several anopheline mosquito species that have different breeding site preferences, different adult resting preferences, and different degrees of anthropophilic behavior. In the case of *An. gambiae*—transmitted malaria in sub-Saharan Africa, the mosquito breeds in small pools of clear, recently collected water, open to the sun for at least part of the day (old water usually contains a myriad of predatory insects, and it may be polluted too, two things that *An. gambiae* larvae dislike).

Most of these water pools are associated with human activities, such as tire tracks, irrigation seepages, cattle hoofprints, and so on. Control of larvae in such conditions may be very difficult because of the scattered nature and small size of the sites. On the other hand, the mosquito *An. funestus*, which occurs in the same areas as *An. gambiae*, breeds in permanent bodies of water and avoids predators by hiding in the emerging vegetation. Cleaning of the edges of ponds or introduction of some fish species can provide some control of *An. funestus* breeding. However, both *An. gambiae* and *An. funestus* are very anthropophilic, and rest inside human dwellings, making this behavior amenable to the use of indoor insecticide spraying to kill the adult mosquitoes. Furthermore, one does not need to kill every mosquito as soon as it emerges. Because of the extrinsic incubation period, and because the daily mosquito survival rate is the most crucial parameter for vector capacity, just making life dangerous for the mosquito may reduce its longevity, and have a large impact on malaria transmission. This rationale was actually the basis for exclusive adulticide use of DDT during the malaria eradication attempt of the 1950s. In fact, use of DDT for larvicidal purposes was discouraged, because it would accelerate DDT resistance.

For indoor spraying with an insecticide, one has to make sure that the insect to be controlled is susceptible to the insecticide. The longevity of the insecticidal action on the treated surface varies with the insecticide used, and this factor is important in determining the periodicity and cost of the applications. There are many standardized tests and kits available from the World Health Organization for determining mosquito susceptibility.

Dengue is transmitted by *Ae. aegypti* and *A. albopictus* mosquitoes. These mosquitoes choose small containers with clean water for laying eggs. They lay their eggs singly just above the water line. The eggs embryonate and can sustain further desiccation for many months. When the container is again flooded, the larvae hatch and are the first insects to exploit the new environment. This is a good strategy for avoiding predators, and for being able to molt to the adult before the container dries again. The eggs have also made international trips in exported used tires, the probable mode of introduction of *Ae. albopictus* into the United States. *Ae. aegypti* prefers containers closely associated with humans, whereas *Ae. albopictus* will breed more in the peridomestic environment. In both cases, sanitation around human habitation, as well as changes in habits (such as emptying water in flower pots and other containers) can reduce mosquito breeding. Indoor spraying for *Ae. aegypti* is also effective, but is not so useful for the more exophilic biter *Ae. albopictus*.

Bancroftian filariasis is transmitted by many species of mosquitoes, but the main vector worldwide is *Culex pipiens quinquefasciatus*. Unlike the mosquitoes mentioned previously, *C. pipiens quinquefasciatus* can survive and thrive in highly organic polluted waters that would kill by suffocation any *Aedes* or anopheline larvae. *Culex* larvae have a strong and long siphon tube that allows them to break through the scum of such breeding sites. Indeed, pit latrines and sewers can lead to breeding of enormous numbers of *Culex* mosquitoes, which can make good use of the organic residue. Sanitation measures as well as larvicides can be of use to control such mosquitoes.

Control of river-dwelling black fly larvae involves the introduction of insecticides at regular intervals in rivers and

streams, making it important to use appropriate doses of these chemicals to prevent damage to other aquatic life. Great improvement in onchocerciasis control in west Africa was achieved by a coordinated multinational effort in treating most of the Volta River basin.

On the other hand, control of Chagas' disease—transmitting bugs is achieved with indoor residual spraying, which kills all stages of the vector. These bugs also need hiding places such as crevices (common in mud and stick houses) to avoid predators (ants, spiders, birds, rodents—it is a dangerous world for bugs out there). Improvement of economic conditions contributes substantially to Chagas' disease control. Chagas' disease control has been very successful in South America where vector transmission in Brazil was enormously reduced following indoor spraying, together with economic and population changes.

In order to avoid vectors, one can modify human behavior or use chemicals or devices to block vector–human contact. Most vectors have a particular time of day when they search for a meal. Some mosquitoes (such as *Ae. aegypti*) prefer to bite at daybreak or sunset, whereas others (such as *C. pipiens*, *An. gambiae*, and *An. dirus*) prefer to bite in the middle of the night. Planning of human activities around these times may pay off greatly. The British in Southeast Asia during World War II never fought by night and avoided malaria, whereas the Japanese troops became severely malarious by going into the forest at a time when *An. dirus* fed.

Repellents are substances that prevent landing, or probing, and feeding by vectors. Some of these substances possibly act by exciting all chemical receptors in the vectors, so the insect does not know what is occurring, rather than being

repelled by a noxious substance. A good repellent has to be volatile, which makes it last a shorter time, and thus frequent applications may be needed for effective control. Some repellents are toxic to children and should be used with care.

Physical means of prevention include house screening and bednets for nighttime-biting vectors. Recently bednets were shown to be more efficient when impregnated with pyrethroid insecticides, and large-scale trials of impregnated bednets for malaria control are being completed. Impregnated bednets are actually an insecticide target device, as the human inside the net acts as bait for the mosquitoes.

It is important to remember that vectors vary considerably in their breeding site choices, as well as in their preferred resting and biting places, and these factors must be taken into consideration for control measures.

## Animal Poisons in the Tropics

ROBERT L. NORRIS  
PAUL S. AUERBACH

The word *tropical* often conjures up visions of mysterious and deadly creatures creeping or slithering through lush vegetation. What adventure movie or documentary about the jungle is complete without a snake, spider, or scorpion? Hazardous tropical creatures also lurk in the ocean surf and among exotic coral reefs. For most travelers to tropical environments, however, venomous creatures are more of a perceived threat than an actual danger. It is the native human populations in tropical regions of the world on which these creatures take their greatest toll. The purpose of this chapter is to provide a practical overview of the planet's most important terrestrial and marine venomous animals and their poisons. The clinical syndromes that may be anticipated and approaches to management are outlined.

### ■ Venomous Snakes

There are approximately 3000 species of snakes, with just over 10% considered dangerously toxic to humans.<sup>1</sup> Venomous snakes are divided into five families, as listed in Table 9-1. All tropical and subtropical and most temperate regions of the world can boast at least one species of venomous snake (Plate 9-1). Notable exceptions include New Zealand, Madagascar, Hawaii, and most of the West Indies.<sup>2</sup>

It is difficult to establish the incidence of venomous snakebite in the world owing to a paucity of reliable data from developing countries. The best estimate to date of worldwide mortality due to venomous snakes comes from a World Health Organization (WHO) report, which suggested 30,000 to 40,000 deaths per year.<sup>3</sup>

#### Snake Venom and the Venom Apparatus

Snake venoms, produced in modified salivary glands in the upper jaw and injected through hollow or grooved fangs, are some of the most complex naturally occurring toxins known. Most contain a mixture of proteins (including enzymes), low-molecular-weight (nonenzymatic) polypeptides, metallic ions, and other substances that continue to be researched.<sup>1</sup> To avoid underestimating the potential of any particular snake's venom, one must recognize the complexity of these toxins and anticipate multisystemic manifestations, as in the following discussion.

Viperid venoms (from the family Viperidae) tend to be rich in enzymes such as phospholipase A<sub>2</sub>, which adversely affects a variety of cell membranes and metalloproteinases, which directly or indirectly promote coagulopathy, hemorrhage, swelling, and necrosis.<sup>1,4,5</sup> Many of the more lethal fractions of viperid venoms are low-molecular-weight polypeptides that act as neurotoxins, cardiotoxins, myotoxins, and hemotoxins.<sup>1</sup> Although elapid venoms (from the family Elapidae) tend to be simpler in composition than those of the viperids, they are extremely potent, especially in terms of neurotoxicity. Elapid neurotoxins can be divided into those that act presynaptically by inhibiting neurotransmitter release and, more commonly, those that act postsynaptically by blocking acetylcholine effects.<sup>6,7</sup> A number of elapid venoms, especially from several species of spitting cobras, do contain enzymatic components that can cause tissue necrosis.<sup>8</sup> Sea snake venoms all appear to be very similar and contain components with highly potent neurotoxins and myotoxins.<sup>9</sup> The venoms of the burrowing asps (family Atractaspidae) and colubrids (family Colubridae) are more poorly studied at this time. It has become clear, however, that some species of Colubridae, a family of snakes largely thought of as being nonvenomous, are dangerously toxic to humans. These include the boomslang (*Dispholidus typus*), the twig snake (*Thelotornis kirtlandii*), and the Asian keelback snakes (genus *Rhabdophis*).<sup>10</sup>

#### Clinical Findings

A summary of potential clinical manifestations following venomous snakebite is presented in Box 9-1.<sup>1,11-14</sup> It is important to keep in mind, however, that snake venom poisoning is a complicated disorder that brings into play a number of variables that determine the clinical manifestations and severity of venom poisoning. Such variables include the composition of the snake's venom (which can vary not only by species but also by age, health, and geographic origin of the snake), the factors that led to the bite, and the victim's overall health and body size.<sup>1</sup> It is interesting to note, however, that venomous snakes often bite without injecting any venom. Such "dry bites" occur in approximately 20% to 30% of viperid bites, 50% of elapid bites, and up to 75% of sea snake bites.<sup>15</sup>

#### Management

First-aid management of venomous snakebite should be aimed at delivering the victim expeditiously to definitive medical care. Beyond that, measures should ideally be judged on their risks vs. benefits. Unfortunately, conclusive studies regarding field management measures for venomous snakebites are sorely lacking. Clearly, however, many techniques recommended in the past are of no proven benefit and may actually worsen the clinical outcome. Examples include incising the bite site, or applying local ice, heat, tourniquets, or electric shocks.<sup>1,16</sup> The victim should be calmed as much as possible, and the bitten extremity can be splinted to limit movement in an effort to reduce pain. While use of mechanical suction has been recommended for many years, evidence suggests that this technique is unable to remove any significant amount of venom from the depot site.<sup>17,18</sup> Furthermore, there is now evidence that mechanical venom extraction devices can cause additional harm to the local tissues.<sup>19</sup>

**Table 9-1** Important Venomous Snakes of the World

Family	Subfamily	Genus	Examples and Comments
Viperidae	Viperinae	<i>Bitis</i>	Old World vipers; Europe; Asia; Africa
		<i>Vipera</i>	
		<i>Echis</i>	
	Crotalinae	<i>Crotalus</i> <i>Agkistrodon</i> <i>Bothrops</i> <i>Trimersurus</i>	Pit vipers; North, Central, South America; Asia Rattlesnake (see Plate 9-1A) North American cottonmouth, water moccasin, and copperhead Central and South American lancehead pit viper Asian pit viper
Elapidae		<i>Naja</i>	Old and New World; All Australian terrestrial venomous snakes
		<i>Dendroaspis</i>	Cobra (see Plate 9-1B)
		<i>Bungarus</i>	Mamba (see Plate 9-1C)
		<i>Micrurus</i>	Krait
		<i>Micruroides</i>	Coral snake (see Plate 9-1D)
		<i>Oxyuranus</i>	Coral snake
		<i>Pseudechis</i>	Taipan
		<i>Pseudonaja</i>	Australian black snake
		<i>Acanthopis</i>	Australian brown snake Death adder
Hydrophidae	Hydrophinae		Sea snake
	Laticaudinae		Sea krait
Atractaspididae			Burrowing asp
Colubridae			A small percentage of this classically “nonvenomous” family bears rear fangs and modified salivary glands that are, in some cases, capable of causing severe envenomation in humans
		<i>Dyspholidus typus</i>	African boomslang
		<i>Thelotornis kirtlandii</i>	African twig snake, vine snake

**Box 9-1** Clinical Findings Following Venomous Snakebite**Viperids (Vipers and Pit Vipers)**

## Signs and Symptoms

- Pain (often “burning”; may be severe; onset usually very early)
- Soft tissue swelling (may be rapidly progressive; usually confined to subcutaneous tissues)
- Nausea and vomiting
- Diaphoresis
- Ecchymosis/petechiae/purpura
- Hemorrhagic blebs, serous vesicles
- Necrosis
- Bleeding (at essentially any anatomical site)
- Difficulty breathing (due to pulmonary edema or neurotoxicity)
- Bradycardia/tachycardia
- Hypotension/hypertension
- Muscle fasciculations
- Paresthesias
- Muscle paresis/paralysis (uncommon with most viperids)

## Laboratory Abnormalities

- Complete blood count: increased hematocrit due to hemoconcentration; decreased hematocrit due to bleeding/hemolysis; decreased platelets (due to consumption); leukocytosis
- Coagulation studies: often abnormal, consistent with consumptive coagulopathy

- Urine: hematuria, myoglobinuria, proteinuria
- Arterial blood gases: in severe cases, hypoxemia, metabolic acidosis
- Others: occasional hyperglycemia and abnormal chemistries consistent with renal dysfunction, liver injury, rhabdomyolysis, cardiac injury

**Elapids**

## Signs and Symptoms

- Pain (may be absent); paresthesias/numbness at bite site
- Soft tissue swelling (usually less than with most viperids)
- Difficulty breathing (due to neurotoxicity)
- Nausea and vomiting
- Diaphoresis
- Muscle fasciculations
- Cranial nerve dysfunction
- Muscle paresis/paralysis (including muscles of respiration)

## Laboratory Abnormalities

- Complete blood count: leukocytosis
- Arterial blood gas analysis: in severe cases, hypoxemia, respiratory acidosis

**Hydrophids (Sea Snakes)**

## Signs and Symptoms

- Similar to elapids, plus significant muscle pain

Continued

**Box 9-1 Clinical Findings Following Venomous Snakebite—Cont'd****Laboratory Abnormalities**

- Chemistries: may demonstrate renal dysfunction (risk of severe hyperkalemia), rhabdomyolysis

***Atractaspids (Burrowing Asps)*****Signs and Symptoms**

- Very similar to viperid venom poisoning, but tend to be less severe

**Laboratory Abnormalities**

- Coagulation studies: may be prolonged/abnormal
- Serum chemistries: may reveal evidence of liver dysfunction
- Arterial blood gases: hypoxia, hypercarbia
- Electrocardiography: conduction abnormalities

***Colubrids*****Signs and Symptoms**

- Local pain
- Soft tissue swelling
- Ecchymosis
- Lymphadenopathy
- Paresthesias
- Gingival bleeding, epistaxis, hematuria, melena, subcutaneous hemorrhage

**Laboratory Abnormalities**

- Serum chemistries: may be consistent with renal failure
- Coagulation studies: depletion of fibrinogen and platelets; increased fibrin degradation products
- Urine: hematuria

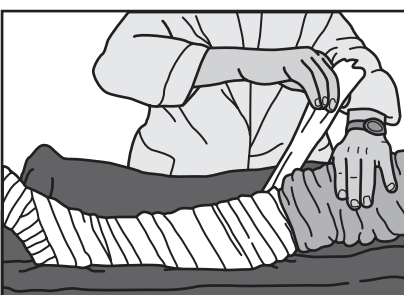

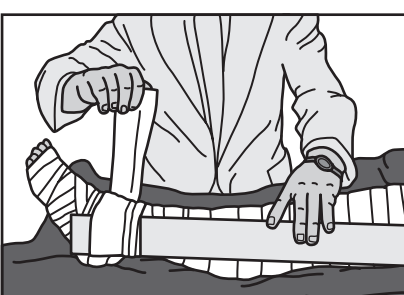

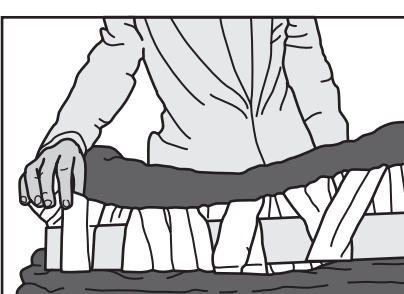

Another previously recommended first-aid technique was the use of a broad constriction band, applied several inches proximal to the bite to occlude superficial venous and lymphatic return without impeding arterial flow. While there is some evidence that this may limit systemic spread of venom,<sup>20</sup> it may worsen distal swelling and potentially increase local necrosis in viperid bites. If a victim is in a remote area and has been bitten by a potentially lethal snake, the best course of therapy would be application of pressure-immobilization (PI)—a technique pioneered by the Australians and illustrated in Figure 9-1.<sup>21</sup> PI has been demonstrated to reduce venom absorption in animal models of elapid and pit viper snakebite,<sup>22,23</sup> and has been reported anecdotally effective in some human cases.<sup>24–27</sup> It should be realized, however, that strict limitation of venom to the depot site could increase local wound damage. In such a case, the local tissues and perhaps even the extremity may be being sacrificed in an effort to save the victim's life. There is evidence that individuals at risk for snakebite should receive special training on the use of PI to increase the likelihood that it will be applied appropriately if needed.<sup>28</sup>

Hospital management of venomous snakebite begins with sound supportive care. Attention should initially be focused on the victim's airway, breathing, and circulation. Cardiac and pulse oximetry monitoring (if available) should be instituted and intravenous (IV) access should be obtained as soon as possible. Following serious bites by many elapids, respiratory failure due to neuromuscular toxicity can be a problem. If victims show any evidence of respiratory distress or difficulty swallowing or handling secretions, the airway should be protected without delay by endotracheal intubation and their respirations should be supported. Hypotension, often due to venous pooling of blood, should be treated initially with crystalloid infusion. If the blood pressure fails to respond to 20 to 40 mL/kg of crystalloid, then albumin should be added to the resuscitation fluids since it may remain in the leaky vasculature for a longer period of time.<sup>29</sup> Only after an adequate trial of fluid resuscitation should vasopressor agents be added. Blood samples should be drawn for appropriate laboratory studies to include complete blood counts, serum chemistries, renal and liver function studies, coagulation profiles, and typing and screening.

After any immediately life-threatening issues are addressed, a more detailed history can be obtained and an attempt made to identify the offending reptile. If the snake has been brought in with the patient, it should be handled with care, for even a decapitated head can have a bite reflex for up to 1 hour.<sup>30,31</sup> In some regions of the world, such as Australia, aid in identifying the offending species comes in the form of snake venom detection kits, which use a colorimetric, enzyme-linked immunosorbent assay (ELISA) technique to identify the presence of venom in serum, urine, or bite site drainage.<sup>32,33</sup>

The bitten extremity should be marked at two or more sites and the circumferences checked every 15 minutes until it is clear that there is no swelling or that all swelling has stabilized. If any device was used on the extremity in the field in an effort to limit venom spread, caution needs to be used during its removal to prevent the sudden release of venom and lactic acid into the central circulation. If a tourniquet was applied, it should be immediately replaced with a proximal, more loosely fitting constriction band in order to get blood flowing back into the extremity. IV access should be obtained before final removal of any constriction band or pressure-immobilization device. If systemic signs or symptoms of venom poisoning are already present, appropriate antivenom administration should be started before device removal (see later discussion). If systemic signs or symptoms develop after a pressure-immobilization device is removed, the device should be reapplied until antivenom can be started.<sup>34</sup>

Antivenom is the primary therapeutic agent for treatment of snake venom poisoning. The decision to administer antivenom is based on the severity of the victim's symptoms, signs, and laboratory abnormalities. If systemic toxicity is evident, envenomation is at least moderate in severity and the need for antivenom is established. If there are no systemic abnormalities and local findings are minimal (and stable) or absent, then the envenomation is probably mild (or lacking altogether) and antivenom can generally be withheld. Care must be exercised in making these decisions as snake venom poisoning is a dynamic process, and a case that presents as an apparent mild poisoning or even dry bite can progress with time to become severe and life threatening. This is especially true for victims of some sea snake, elapid, and colubrid bites, in whom the onset of symptoms may be delayed for hours.<sup>35,36</sup>

Bites to the lower limb	
	<p>1. Apply a broad pressure bandage over the bite site as soon as possible. Crepe bandages are ideal, but any flexible material may be used. Clothing, towels, etc. may be torn into strips. Pantyhose have been successfully used.</p> <p>Do not take off clothing, as the movement of doing so will promote the movement of venom into the bloodstream. Keep the bitten limb, and the patient, still.</p> <p>Bandage upward from the lower portion of the bitten limb. Even though a little venom may be squeezed upward, the bandage will be more comfortable, and therefore can be left in place for longer if required.</p>
	<p>2. The bandage should be as tight as you would apply to a sprained ankle.</p>
	<p>3. Extend the bandage as high as possible up the limb.</p>
	<p>4. Apply a splint to the leg. Any rigid object may be used as a splint: spade, piece of wood or tree branch, rolled up newspapers, etc.</p>
	<p>5. Bind it firmly to as much of the leg as possible.</p> <p>Keep the patient still. Lay the patient down to prevent walking or moving around.</p>

**FIGURE 9-1** The Australian pressure-immobilization technique for field management of bites and stings by venomous snakes, funnel-web spiders, dangerous scorpions, the box jellyfish, cone snails, and the blue-ringed octopus. (Used with permission from Dr. Ken Winkel, Director, Australian Venom Research Unit, Department of Pharmacology, University of Melbourne [www.avru.org].)

<b>Bites to the hand or forearm</b>	
	<p>Bandage as much of the arm as possible, starting at the fingers.</p> <p>Use a splint to the elbow. Use a sling to immobilize the arm.</p> <p>Keep the patient still. Lay the patient down to prevent walking or moving around.</p>
<b>Bites to the trunk</b>	<p>If possible apply firm pressure over the bitten area. Do not restrict chest movement. Keep the patient still.</p>
<b>Bites to the head or neck</b>	<p>No first aid for bitten area. Keep the patient still.</p>

FIGURE 9-1 Cont'd.

Antivenoms are either monovalent (covering a single species) or polyvalent (providing coverage for multiple species). An example of a wide-spectrum, polyvalent product is CroFab (Savage Laboratories, Melville, NY), which provides excellent coverage for all North American pit vipers and may be protective in bites by some Central and South America species as well.<sup>37</sup> With few exceptions, there is little to be gained by administering an antivenom that is not designed for use against the offending snake species. A notable exception to this is the efficacy of Australian tiger snake (*Notechis scutatus*) antivenom for sea snake envenomations.<sup>38</sup>

All currently available snake antivenoms are produced from either horse or sheep serum and therefore carry some risk of allergic phenomena (anaphylactic or anaphylactoid reactions or serum sickness; see later discussion). While some (but not all) antivenom manufacturers suggest an intradermal test to predict possible allergy to their products, the sensitivity and specificity of such skin tests are poor.<sup>31,39,40</sup> If a patient has a serious bite and clearly needs antivenom, administration should start without waiting the 20 to 30 minutes it takes to apply and read a skin test.

Before giving antivenom, informed consent should be obtained from the patient when possible and an appropriate dose of epinephrine should be drawn up at the bedside for use in the event of an anaphylactic/anaphylactoid reaction. The patient's intravascular volume should be expanded with crystalloid fluids if his or her cardiovascular status permits.<sup>41</sup> Patients can be premedicated with IV antihistamines (both H<sub>1</sub> and H<sub>2</sub> blockers) if the risk of allergy is felt to be particularly high (as with the use of some less purified products containing more extraneous heterologous proteins, or in a patient with a known allergy to horses or sheep). Premedicating with steroids is of no benefit due to their delayed onset of action.

Snake antivenom should always be given IV, as there is no benefit to local administration,<sup>42</sup> and intramuscular injection results in slower and lower levels of circulating protective antibodies.<sup>43</sup> Guidelines for appropriate starting doses of antivenom can be obtained from product package inserts.

The dose to be given should be diluted in approximately 250 to 1000 mL of 5% dextrose in water or saline (approximately 20 mL/kg for young children). The infusion is started very slowly with the physician at the bedside to intervene immediately if an adverse reaction occurs. If the serum is tolerated during the first several minutes of infusion, the rate is increased to complete the infusion in 1 to 2 hours. Further antivenom may be necessary depending on the progression of clinical findings or laboratory abnormalities that might occur following the initial dose. Some manufacturers recommend scheduled redosing of antivenom once initial control of poisoning has been obtained.<sup>44</sup> When adequate antivenom has been administered, the patient generally begins to feel subjectively better and clinical findings stabilize or normalize.

If an anaphylactic/anaphylactoid reaction to the antivenom should occur, the infusion should be immediately halted and the reaction treated in standard fashion with fluids, epinephrine, and further antihistamines as necessary. In this setting, steroids should be given to blunt any delayed second-phase allergic reaction that might occur.<sup>45</sup> Once the reaction is halted, antivenom can often be restarted if necessary based on the severity of venom poisoning.<sup>31</sup> In this scenario, it may help to further dilute the antivenom and run the infusion at a slower rate.

When a victim of severe venom poisoning develops an acute allergic reaction to antivenom, the physician has two choices. Antivenom can be withheld with reliance on supportive care alone. Alternatively, the patient can be placed in an intensive care setting with invasive hemodynamic monitoring and antivenom can be slowly administered while suppressing the reaction with a titrated epinephrine infusion.<sup>46</sup> Consultation with an allergist or toxicologist is helpful. Attempting to desensitize the patient with gradually increasing doses of antivenom is too protracted a process to be beneficial.<sup>31</sup>

Wound care of the bite site includes splinting the extremity with cotton padding between the digits and elevating if soft tissue swelling is present. Tetanus status should be updated as necessary. Prophylactic antibiotics are not necessary.<sup>1,47,48</sup>

Hemorrhagic blebs or serous-filled vesicles should be debrided at 3 to 5 days.<sup>49</sup> Physical therapy is vital to optimal functional recovery and should begin as soon as the patient's condition allows.

Most swelling in snakebites is localized to the subcutaneous tissues. In some cases, however, (especially bites by larger viperids) venom may be deposited deeper into muscle compartments, causing swelling within the confined space.<sup>1</sup> A swollen, ecchymotic, painful extremity may suggest an impending compartment syndrome. In such cases, intracompartmental pressures (ICPs) should be objectively measured (e.g., with a wick catheter). If ICPs exceed capillary perfusion pressure (i.e., greater than approximately 30 mm Hg in a normotensive patient), the extremity should be elevated, antivenom should be given, and a trial of IV mannitol (1 g per kg body weight) can be given (if the patient's blood pressure is adequate). If the victim's ICPs do not return to an acceptable range within one hour of such therapy, a fasciotomy is indicated. Fortunately, this is rarely required.<sup>50</sup>

All patients with evidence of venom poisoning should be admitted to the hospital. Whenever possible, patients who require antivenom or have the potential for sudden cardiovascular or respiratory decompensation should be admitted to an intensive care setting. Owing to the delay in onset of clinical findings with many elapid, sea snake, and some dangerous colubrid species, any victim bitten by one of these should be observed for 24 hours. Following viperid bites, reliable victims who are totally asymptomatic with normal clinical and laboratory findings after 6 hours of observation can be discharged with a responsible adult and instructions to return immediately if symptoms appear. Admitted patients should be closely observed and laboratory values should be rechecked every few hours until stable. Each time the victim voids or defecates, bedside tests to rule out occult blood (as a sign of coagulopathy) should be performed.

At discharge, all victims who received antivenom should be warned of the signs and symptoms of serum sickness. If these occur, they should be treated with steroids until all findings resolve, followed by a weeklong taper. Antihistamines and analgesics may be helpful for symptomatic relief. Any victim who developed a coagulopathy during the acute stage of venom poisoning should be warned that coagulopathy can recur for up to two weeks following envenomation.<sup>51</sup> Such patients should watch for any signs of clinical bleeding and avoid any unnecessary surgery for the next few weeks.

## ■ Venomous Lizards

There are only two species of venomous lizards in the world, the Gila monster (*Heloderma suspectum*) and the Mexican beaded lizard (*Heloderma horridum*; Plate 9-2). Gila monsters are found from the southwestern United States into northern Mexico, while beaded lizards are located from central to southern Mexico.<sup>52</sup>

The anatomy, habits, and venoms of these two species are similar, though *H. horridum* reaches substantially larger sizes than does *H. suspectum*. The venom apparatus consists of a pair of multilobar glands in the anterior aspect of the lower jaw with ducts that conduct venom to the bases of teeth on the anterior mandible.<sup>14,53</sup> These loosely attached teeth are

grooved to facilitate envenomation. When biting, the lizard may hang on tenaciously and chew, and teeth may be left behind in the wounds. The venom, less complex than most snake venoms, contains hyaluronidase, phospholipase A, proteases, kallikrein, and serotonin.<sup>14,53</sup>

Signs and symptoms of helodermatid venom poisoning may include severe, immediate pain; mild to moderate soft tissue swelling; lymphangitis; local vasospasm; a generalized feeling of weakness; anxiety; nausea and vomiting; tachycardia; tachypnea; and hypotension.<sup>1,53,54</sup> As with snakes, dry bites may occur.<sup>1,54</sup>

The first step in managing the bite of one of these lizards may involve extracting the tenacious creature from the victim's anatomy. This can be accomplished by prying the animal's jaws apart, holding a flame beneath its lower jaw, or submerging the animal in cold water.<sup>55</sup> No first-aid measures are of any proven efficacy, and attention should be directed at delivering the patient as soon as possible to medical care.

Life-supporting measures should be instituted, including endotracheal intubation if necessary (e.g., in the case of profound cardiovascular collapse). Hypotension is treated with IV crystalloid infusion. As with snakebites, albumin may be effective in refractory shock, and pressors are rarely required.<sup>1,53</sup> Laboratory evaluation may reveal a leukocytosis, and coagulation values are usually normal.<sup>1</sup> An electrocardiogram should be obtained, as acute myocardial infarction has been reported following helodermatid bite.<sup>56</sup>

Wounds should be cleansed and irrigated when possible. Punctures can be explored under local anesthesia to rule out retained teeth. While soft tissue radiographs may help in this regard, they are not 100% sensitive.<sup>53</sup> Tetanus status should be updated, but prophylactic antibiotics are unnecessary.<sup>1</sup> Wounds should be dressed and splinted, and adequate analgesics initiated. There is no commercially available antivenom for these bites. Patients with systemic toxicity should be admitted to the hospital, while those with only local findings after several hours of observation can be discharged to a reliable setting with instructions to return if they worsen. Mortality is exceedingly rare and tissue necrosis is not typically seen.<sup>1,55</sup>

## ■ Venomous Arthropods

The phylum Arthropoda is truly a cosmopolitan group and comprises approximately 80% of the world's known animal species.<sup>57</sup> Of the venomous arthropods, those of the classes Arachnida (including spiders and scorpions) and Insecta (the stinging insects of the order Hymenoptera) are of major medical importance.

### HYMENOPTERA

A significant percentage of the world's population is at risk of life-threatening anaphylactic reactions to Hymenoptera stings. In the United States, for example, somewhere between 0.5% and 5.0% of the population is severely allergic to these venoms.<sup>58</sup> The three superfamilies of major medical importance in this order are the Apoidea (honeybees and bumblebees), the Vespoidea (wasps, yellow jackets, and hornets), and the Formicoidea (ants).

Hymenoptera venoms are complex mixtures of biogenic amines (e.g., acetylcholine, histamine, and serotonin),

polypeptides (e.g., melittin and apamin), and enzymes (e.g., phospholipase, hyaluronidase).<sup>59</sup> Fire ant venom is composed primarily of piperidine alkaloids.<sup>59</sup> The venoms of species within a family are very similar and tend to cause more cross-reaction in allergic patients than do venoms from different families.

The types of reactions that can be seen following Hymenoptera stings include a typical, local reaction marked by transient pain, redness, and swelling; a more extensive local reaction with swelling beyond the sting site; a type I (immunoglobulin E-mediated) anaphylactic response with any combination of diffuse urticaria, angioedema, laryngeal edema, bronchospasm, or hypotension; and a delayed, probably immune complex-mediated, reaction.<sup>60</sup> Examples of such delayed reactions include serum sickness and very rare atypical phenomena such as hemolysis, thrombocytopenic purpura, and poorly understood neurologic syndromes such as Guillain-Barré syndrome or transverse myelitis.<sup>59</sup>

Multiple Hymenoptera stings can produce systemic poisoning. Of special interest in this regard are the Africanized honeybees (*Apis mellifera scutellata*), or "killer bees." These bees are located from Argentina northward into the southern United States and differ from domesticated honeybees in that they attack aggressively with less provocation and press an attack to extreme limits, both in terms of the number of bees involved and the distance and time over which they will pursue a victim.<sup>57,61</sup> Their venom, however, appears to be nearly identical to that of the domesticated bee.<sup>57</sup> Systemic poisoning may produce vomiting and diarrhea, headache, abdominal or uterine cramping, diffuse edema, bronchospasm, cardiovascular collapse, and seizures and may initially be difficult to differentiate from an anaphylactic reaction.<sup>60,62,63</sup> The median lethal number of Africanized bee stings has been estimated to be 19 per kilogram body weight.<sup>64</sup>

Fire ant stings are usually multiple owing to this species's habit of swarming onto an intruder and stinging in concert upon release of a pheromone alert signal. Typical local findings following such stings are slightly painful or pruritic papules that become sterile pustules or vesicles over approximately 24 hours. The epidermal covering sloughs in 2 to 3 days, and healing follows.<sup>65</sup>

## Management

First-aid measures for routine Hymenoptera stings involve limiting distribution of venom and treating pain and itching. Any retained stinger (common with honeybee stings) should be quickly removed from the wound,<sup>66</sup> and ice should be applied. If a known allergic individual sustains a sting or an anaphylactic reaction occurs in the absence of advanced medical capabilities, a lympho-occlusive constriction band should be applied proximally to the extremity (if possible). If more advanced measures are available in the field, care should proceed per the following discussion. Victims possessing epinephrine self-administration kits should be assisted in their use. All patients with systemic findings following stings should be transported to the hospital as quickly as possible.

Hospital management of a simple local reaction involves continuing cold applications, updating tetanus status as indicated, and the use of antihistamines and mild analgesics as necessary. Secondary infections are rare. Large local reactions can be similarly treated, though oral steroids for a few days

are helpful if the symptoms are particularly distressing to the patient.<sup>60</sup>

Anaphylaxis following Hymenoptera stings represents a true emergency, requiring aggressive management of the patient's airway and circulation. Endotracheal intubation is indicated if significant respiratory distress or laryngeal edema or stridor is present. Epinephrine should be administered as soon as available (0.01 mL/kg of a 1:1000 solution intramuscularly, up to a maximum dose of 0.5 mL). If the patient is in profound shock, the epinephrine dose can be diluted to 10 mL and given slowly IV (over 5 to 10 minutes) or an epinephrine infusion can be started and titrated to effect. Hypotensive patients require IV fluid resuscitation and possibly further pressor support. Antihistamines (both H<sub>1</sub> and H<sub>2</sub> receptor blockers) should be started as well. Steroids, orally or intravenously, should be given in an effort to blunt any delayed second phase of anaphylaxis that might occur at 1 to 38 hours following the sting.<sup>45</sup> Patients with significant systemic reactions (e.g., bronchospasm, hypotension, or upper airway swelling) should be hospitalized for further observation. In less severe cases, if the victim is asymptomatic 4 hours after treatment, he or she can be discharged to a reliable environment with instructions to return immediately if symptoms recur.<sup>59</sup> A continued 3-day course of antihistamines and steroids should be prescribed, and the patient should receive an epinephrine self-administration kit (as well as detailed instructions in its use). Patients with systemic reactions should be referred to allergists for potential immunotherapy and should be urged to wear medical alert medallions stating their Hymenoptera allergy. It appears that pediatric patients with systemic reactions limited to dermal manifestations (urticaria) are at no greater risk of developing more severe reactions on re-sting than is the general population, and thus do not need allergy referral<sup>60</sup> (though they should still be prescribed an epinephrine self-administration device). Serum sickness usually presents within 1 week of the sting and may be manifested by urticaria, myalgias, arthralgias, fever, headache, and occasionally renal or neurologic dysfunction. Symptoms can generally be well controlled with oral steroids and antihistamines.<sup>60</sup>

Victims receiving multiple stings and having evidence of systemic toxicity must receive supportive care including oxygen, airway maintenance, and blood pressure support as needed. Hypotension is treated with brisk IV crystalloid infusion and pressor support (epinephrine). These cases often present in similar fashion to anaphylactic shock and can be managed in like fashion.<sup>67</sup>

## SPIDERS

While the majority of the many thousands of spider species of the world are venomous, only a few are of major medical importance. Most species lack fangs of sufficient size to penetrate human skin. Two genera of nearly worldwide distribution are of major significance, the widow spiders (*Latrodectus* spp.) and the brown spiders (*Loxosceles* spp.).

### Widow Spiders

Widow spiders, with at least 10 species and subspecies, are found from Canada all the way through South America,

widely throughout Africa, in the warmer regions of Europe and Asia, and in Australia.<sup>68,69</sup> This is a cosmopolitan spider that is easily transported from one part of the world to another and may be established in areas outside its natural range.<sup>70</sup> It is the female widow spider that poses a threat to humans, as the male is too small to bite through human skin. All female widow spiders have a similar body habitus—a small cephalothorax with a globular abdomen and long, spindly legs (Plate 9-3A). These spiders build sticky, disorganized webs and most victims are bitten when they accidentally contact the web and excite or threaten the spider. The best-known species, and the one on which the majority of research has been done, is the black widow species, *Latrodectus mactans*. In Australia, the indigenous *Latrodectus* species (*L. hasselti*) is known as the redback spider.

The venoms of the different species of widow spiders are all very similar in composition and toxic effects.<sup>71,72</sup> While there are multiple components, the most deleterious is a potent neurotoxin, alpha latrotoxin, which acts at nerve terminals to stimulate the release of neurotransmitters, such as acetylcholine and norepinephrine, resulting in depletion of synaptic vesicles and ultimate blockade of nerve conduction.<sup>72</sup> There is no necrotic or hemolytic component.

The spider's bite is often unnoticed by the patient or may be felt as a slight "pinprick." Local visible tissue changes are minimal. Within an hour, the victim develops local pain that builds in intensity and radiates to regional muscle groups. Bites to the lower extremities may result in significant abdominal muscle pain and spasm, while bites to the upper limbs tend to cause chest pain and tightness (occasionally to the point of dyspnea). Pain peaks after several hours. Vital signs may reveal any combination of tachypnea, tachycardia, hypertension, or fever. Hypertension can be severe enough to precipitate cerebrovascular accidents, congestive heart failure, or myocardial ischemia. Also reported are headache, diaphoresis, nausea, vomiting, restlessness, anxiety, periorbital edema, hyperreflexia, dysrhythmias, and a scarlatiniform or morbilliform skin rash.<sup>73-75</sup> Without treatment, clinical findings (particularly pain) may last up to 72 hours.<sup>41</sup>

## Management

There are no first-aid measures of proven benefit for widow spider bites, though local ice may reduce pain. Any victim developing symptoms beyond local mild discomfort should seek prompt medical care.

In the hospital, the victim's airway and cardiorespiratory systems must be evaluated and stabilized as necessary. Attention can then be directed at relieving painful muscle spasms. A number of analgesic approaches have been tried with varying success. While there have been anecdotal successes with the administration of calcium gluconate,<sup>76,77</sup> its overall efficacy appears quite limited.<sup>73,78</sup> A combination of narcotic analgesics and benzodiazepines appears more efficacious.<sup>73</sup> Antivenom (see later discussion) is the fastest, most effective means of relieving significant pain following these bites.<sup>79</sup>

There are no laboratory studies of diagnostic benefit, but the complete blood count often reveals a leukocytosis, and the blood sugar is frequently elevated. Serum creatinine phosphokinase elevations may also be seen, as well as microscopic hematuria and proteinuria. An admission electrocardiogram

and chest radiograph are advisable in any victim with evidence of systemic poisoning or with significant underlying medical problems.<sup>41,69,80</sup>

Antivenoms for widow spider bites are produced in several countries, and it appears that these antisera are effective in reversing systemic effects and pain regardless of which *Latrodectus* species is involved.<sup>2,79</sup> All of these agents are heterologous serum products, generally produced in horses, and thus carry some risk of inducing allergic reactions (anaphylactoid responses or serum sickness) in patients. Administration should be done cautiously, according to the manufacturer's recommendations, and with immediate availability of epinephrine.

The indications for administering *Latrodectus* antivenom are somewhat controversial. In the United States, many physicians prefer to withhold antivenom in all but the most serious cases, relying instead on supportive care to see the patient through this rarely fatal disease.<sup>79</sup> In Australia, however, redback spider antivenom is used in the majority of significant bites by these spiders and even in cases where a spider has not been identified, but the patient's presentation is consistent with *Latrodectus* venom poisoning.<sup>81</sup> At the very least, widow spider antivenom should be considered for use in very young or very old patients, patients with obviously severe clinical presentations, patients with severe underlying diseases (cardiac disease, hypertension, obstructive pulmonary disease, etc.), and pregnant women (widow spider venom is a potent abortifacient).<sup>82-84</sup>

Admission to the hospital is advisable for patients with significant symptoms (including pain), particularly very young or very old victims, or those with major underlying medical problems.<sup>85</sup> Adult patients in otherwise good health, with normal vital signs and mild symptoms, can be discharged to a reliable setting. They should follow a course of bed rest and should return if symptoms worsen. All patients should have their tetanus status updated as indicated. The current mortality rate from widow spider venom poisoning is very low,<sup>82,86</sup> though full recovery may take several months.<sup>87</sup>

## Brown Spiders

The exact number of brown spider species in the world is unclear, but may exceed 100.<sup>88</sup> They are found in North, Central, and South America; in Europe; in Mediterranean countries; and rarely in Australia.<sup>89,90</sup> The most studied species is the brown recluse (*Loxosceles reclusa*; Plate 9-3B). Most *Loxosceles* are characterized by a violin-shaped marking on the dorsal aspect of the cephalothorax and by the presence of three pairs of eyes (vs. four pairs in most other spiders). Adults are 10 to 15 mm in length and have a leg span of 2 to 3 cm. Unlike widow spiders, both the male and female are dangerous. They are, however, shy and reluctant to bite unless severely antagonized. Most victims are bitten during sleep when they roll over onto a spider in the bed linen or when they put on an article of clothing in which the spider has taken up residence.<sup>91</sup>

*Loxosceles* venoms, though immunologically distinct, all contain a potent enzyme, sphingomyelinase D, which is probably responsible for cutaneous and subcutaneous tissue necrosis and, in rare cases, hemolysis.<sup>90,92</sup> Dermonecrosis is a result of both venom toxicity and autopharmacologic

phenomena within the victim, and appears to involve a cascading pathway of local microvascular damage, complement activation, and stimulation of polymorphonuclear leukocytes (PMNs). Despite the dermonecrotic reputation and potential of this spider's venom, most bites actually result in insignificant lesions that heal spontaneously and completely.<sup>90</sup>

The actual bite is usually painless, and therefore few offending spiders are identified. Within several hours, pruritus, tingling, mild swelling, and redness or blanching at the site may develop.<sup>90,93</sup> During this time, as local tissue ischemia develops, variable pain and tenderness are noted. Within 12 to 18 hours, a small, central blister (clear or hemorrhagic) often forms at the site, surrounded by an irregular zone of erythema or ecchymosis and edema. Within a few days, aseptic necrosis is evident at the bite site with an overlying black eschar. When the eschar sloughs, an open ulcer or crater is left, which may require weeks to months to heal.<sup>90,93</sup> Bites are most severe in fatty regions of the body (buttocks, thighs, etc.).<sup>93</sup> Necrosis rarely involves deeper, more vital structures such as muscles or nerves.<sup>94</sup> Treating physicians faced with a patient with a necrotic wound of unclear etiology should be very careful not to label it as a "brown recluse bite" unless the offending spider has been produced. A better term might be "presumed spider bite" or "presumed arthropod envenomation."<sup>95,96</sup>

Systemic poisoning, termed *viscerocutaneous loxoscelism*, is uncommon, but may be rapidly progressive and severe, especially in children.<sup>71</sup> Onset is generally 24 to 72 hours after the bite and may occur in the absence of any significant cutaneous lesion.<sup>97</sup> Symptoms may resemble a viral illness, with chills, fever, headaches, nausea and vomiting, myalgias, arthralgias, malaise, and weakness. Severe toxicity can lead to hemolysis, thrombocytopenia, disseminated intravascular coagulation (DIC), renal failure, and shock.<sup>90,98</sup>

## Management

Prehospital management should focus on local cooling measures to reduce the enzymatic activity of sphingomyelinase D in an attempt to reduce necrosis.<sup>99</sup>

Most victims with a *Loxosceles* bite present with a small- to medium-sized, painful, necrotic-appearing skin lesion of several hours' to a few days' duration. While an in vitro lymphocyte transformation test can confirm a *Loxosceles* bite in patients at approximately 6 weeks after the bite,<sup>100</sup> there is currently no clinically available laboratory method of making the diagnosis on initial presentation. Work continues in an effort to develop a rapid clinical test that can reliably identify when a *Loxosceles* spider is the etiology of a victim's necrotic lesion.

Vital signs should be checked, looking for any evidence of systemic toxicity (tachycardia, tachypnea, hypotension, fever). Laboratory workup should include a complete blood count, platelet count, and urinalysis. If there is evidence of DIC, hemolysis, or hemoglobinuria, further studies should be obtained, including coagulation studies, electrolytes, blood urea nitrogen, serum creatine, blood sugar, liver function tests, and serum haptoglobin, and blood should be typed and screened. The white blood cell count may be elevated and the hemoglobin may drop dramatically in systemic loxoscelism.<sup>71,90</sup>

Controversy abounds over the proper management of brown spider-induced dermonecrosis, and it is important that patients understand that nothing has been definitively proven to limit the degree of tissue damage that may result. Most bites do well with sound conservative wound care measures (cleansing, sterile dressing, splinting, and tetanus prophylaxis as necessary).<sup>49</sup> Local cooling of the bite site should be initiated and continued intermittently for approximately 72 hours.<sup>99</sup> Antibiotic use is controversial, but is certainly indicated if there is any evidence of secondary infection.<sup>49,99</sup> Wound treatment measures that have been recommended in the past include steroids, dapsone, surgery, and hyperbaric oxygen therapy. Steroids, by any route (systemic or intralesional), are of no demonstrated benefit in limiting necrosis.<sup>49,90</sup> Dapsone and colchicine are also unproved but of theoretical benefit owing to their ability to inhibit PMN function.<sup>49,90,101,102</sup> Dapsone can, however, cause dose-dependent hemolytic anemia and methemoglobinemia and is not approved in the United States for use in *Loxosceles* bites.<sup>103,104</sup> It should be reserved for severe lesions in adults.<sup>90</sup> Initial dosage should not exceed 50 mg to 100 mg orally per day (divided every 12 hours), and a glucose-6-phosphate dehydrogenase level should be checked at the time therapy is started.<sup>103</sup> Treatment should continue until the lesion heals or is grafted.<sup>97</sup>

The temptation to surgically excise the bite site in its early stages should be resisted, as it is impossible to predict the extent and ultimate severity of the lesion left to its natural course.<sup>105</sup> Severe-appearing lesions may regress spontaneously with minimal residual scarring.<sup>98</sup> To optimize chances of healing, any required skin grafting should be delayed 6 to 8 weeks until the necrotic process has been completed.<sup>49</sup> Hyperbaric oxygen therapy may be beneficial in severe wounds.<sup>49,106,107</sup> There is, at present, no commercially available *Loxosceles* antivenom in the United States, but a Brazilian antivenom (a polyvalent product that also covers *Phoneutria* spider bites and *Tityus serrulatus* scorpion stings; see later discussion) for *Loxosceles reclusa* and *L. rufescens* does exist,<sup>108</sup> and it is hoped that continued research will yield an effective antivenom for use in any *Loxosceles* bite,<sup>109</sup> particularly if a technique can be developed to identify with certainty the cause of the lesion when patients present without having seen the spider.<sup>110,111</sup>

Management of viscerocutaneous loxoscelism is primarily supportive—ensuring adequate hydration, maintaining electrolyte balance, and giving analgesics as necessary. A short course of systemic steroids (e.g., prednisone, 1 mg/kg/day for 2 to 4 days) may help stabilize erythrocyte membranes and lessen the severity of hemolysis.<sup>71,90,98</sup> Blood products may be needed to treat anemia or thrombocytopenia, and heparin may be added if DIC develops.<sup>90</sup> Hemoglobinuria may necessitate alkalization of the urine, and dialysis may be required in the face of acute renal insufficiency, though it does not remove venom or hemoglobin from the circulation.<sup>90</sup>

Patients without evidence of systemic toxicity or severe necrosis may be followed as outpatients with daily wound checks, monitoring blood counts, and urinalyses for several days.<sup>90</sup> Patients with systemic toxicity or rapidly expanding lesions should be admitted and have close monitoring for laboratory abnormalities.<sup>105</sup> While there have, to date, been no documented deaths in patients bitten by positively identified

brown spiders in the United States, it is clear that *Loxosceles* spiders are capable of severe envenomation, with real potential for mortality, especially in small children.<sup>74</sup>

### Miscellaneous Spiders

Other spiders of medical interest include the Australian funnel web spiders (genera *Atrax* and *Hadronyche*), the South American hunting or banana spiders (*Phoneutria* spp.), the aggressive house spider of the U.S. Pacific Northwest (*Tegeneria agrestis*), the wolf spiders (family Lycosidae), and the tarantulas.

The funnel web spiders of Australia and Tasmania are relatively large spiders that can inflict a very painful and potentially fatal bite.<sup>68</sup> The venom is a neurotoxin that stimulates neurotransmitter release from the autonomic nervous system and at neuromuscular junctions.<sup>74</sup> Effects may include salivation, lacrimation, nausea and vomiting, abdominal pain, diarrhea, restlessness, hypertension, muscle twitching, dyspnea, and confusion.<sup>74,89</sup> First-aid therapy involves use of the pressure-immobilization technique (as outlined for snakebites previously), application of ice, and prompt transportation to the hospital.<sup>89</sup> An antivenom is produced in Australia and is effective in severe bites.<sup>89,112</sup>

South American spiders of the genus *Phoneutria* (wandering spiders, huntsman spiders, or banana spiders) can be dangerous.<sup>74</sup> They are large and aggressive, and possess a potent neurotoxic venom that produces severe pain and autonomic overdrive.<sup>74,108</sup> Management may include local anesthetic infiltration, application of local heat, and administration of systemic analgesics or sedatives, or both.<sup>108</sup> There is an antivenom produced in Brazil that is effective for severe bites,<sup>108</sup> which are more likely to occur in very young and very old patients.<sup>113</sup>

While commonly feared because of their large size and “hairy” appearance, most tarantulas (of the suborder Orthognatha) are relatively harmless. While bites can be painful, necrosis and systemic reactions are rare. A problem with many tarantulas is their habit of flicking fine hairs off the dorsum of their abdomens towards a perceived threat. If these “urticating” hairs enter the eyes or mucous membranes, they can cause itching and irritation on both an allergic and a mechanical basis.<sup>105</sup> These barbed, urticating hairs can also penetrate the cornea and cause an acute keratouveitis.<sup>114</sup>

Without doubt, there is still much that needs to be learned about the medical importance of poorly studied spider species. Some species that were previously thought to be medically important have been exonerated of their unjust reputations. Wolf spiders (*Lycosa* spp.) were for some time suspected of causing necrotic lesions in Brazil, but it is now understood that these large hunting spiders are relatively harmless,<sup>115</sup> and it was likely *Loxosceles* spiders causing these clinical findings. Similarly, the white-tail spider in Australia was, for years, erroneously thought to cause necrotic arachnidism, and this has only recently been definitively refuted.<sup>116,117</sup> On the other hand, it has been within the last two decades that the importance of the aggressive house spider or hobo spider (*T. agrestis*) of the U.S. Pacific Northwest has come to light as a cause of necrotic and systemic arachnidism.<sup>118</sup>

Besides the few spider species for which specific therapy exists, such as antivenom for *Latrodectus* bites, the management

of spider bites is largely conservative—tetanus prophylaxis, ice, mild analgesics, standard wound care, and antibiotics if secondary infection occurs.

### SCORPION VENOM POISONING

There are an estimated 1500 species of scorpions in the world, but only about 25 of these are dangerously toxic to humans.<sup>119</sup> The medically important species in the Old World fall into the genera *Buthus*, *Androctonus*, *Leiurus*, and *Buthotus*, and in the New World, *Centruroides* (Plate 9-3C) and *Tityus* are important.<sup>120</sup>

Scorpion venoms have received much research attention in recent years as efforts to isolate the various components proceed. The venoms of scorpions posing a serious threat to human life possess toxins with significant neurologic and cardiovascular effects. These venoms stimulate massive release of neurotransmitters from autonomic nerve terminals, neuromuscular junctions, and the adrenal medulla, resulting in sympathetic, parasympathetic, and paralytic signs and symptoms.<sup>105,120</sup> Pain is a common immediate symptom and may be enhanced by the presence of serotonin in many venoms.<sup>120</sup> Paresthesias may occur as well. Systemic findings are related to venom-induced release of acetylcholine and catecholamines. Such findings may include restlessness, anxiety, roving eye movements, hypersalivation, diaphoresis, nausea, vomiting, hypertension, bradycardia, tachycardia, dysrhythmias, hyperthermia, muscle fasciculations, alternating opisthotonos and emprosthotonos, weakness, paralysis, difficulty speaking or swallowing, dyspnea, wheezing, stridor, pulmonary edema, coma, and death.<sup>120-122</sup> Stings by less toxic scorpions usually result in immediate burning pain and mild local soft tissue swelling or ecchymosis. Allergic reactions to scorpion stings are extremely uncommon.<sup>123</sup> Necrosis is also rare, with the exception of a poorly studied scorpion from Iran and Iraq, *Hemiscorpius lepturus*.<sup>74,124</sup>

### Management

First-aid measures for scorpion stings should include local cooling to reduce pain. For neurotoxic scorpions, the Australian pressure-immobilization technique may be beneficial.<sup>89</sup> If the offending scorpion can be safely captured, identification may guide further management.

In the hospital, vital signs should be checked and frequently monitored. Physical examination should assess manifestations of sympathetic, parasympathetic, or neuromuscular excitation. There are no laboratory studies of diagnostic value. Routine tests, if obtained, may demonstrate an increase in white blood cell count, serum glucose, serum amylase, creatinine phosphokinase, renal function values, and mild abnormalities in coagulation values.<sup>122,125</sup> Cerebrospinal fluid pleocytosis has been reported.<sup>122</sup> Victims displaying only local symptoms can be treated on an outpatient basis with ice and appropriate analgesics. Tetanus status should be updated as necessary.

Patients with evidence of systemic envenomation should receive oxygen and cardiac and pulse oximetry monitoring, and should have an IV line established. Endotracheal intubation may be necessary in the face of impending respiratory failure or excessive airway secretions.<sup>122</sup> Central nervous

system (CNS) symptoms such as anxiety, restlessness, muscular hyperactivity, and moderate hypertension can usually be treated with bed rest and sedation.<sup>122</sup> Sedative doses of IV benzodiazepines or phenobarbital can be used with close monitoring of respiratory status.<sup>125</sup> Though their efficacy is unproved, adrenergic blocking agents have been recommended for hemodynamically significant supraventricular tachycardia.<sup>120</sup> Antihypertensive agents may be necessary if sedation fails to resolve severe blood pressure elevation.<sup>85</sup> Shock and pulmonary edema may occur in severe cases and may mandate invasive hemodynamic monitoring for adequate resuscitation.<sup>126</sup> Analgesics should be administered as necessary, but narcotics should be given cautiously as there is some evidence of synergistic action with some scorpion venoms.<sup>127</sup>

In many areas of the world, such as South America, Saudi Arabia, India, and Mexico, antivenoms have been prepared against the more dangerous scorpion venoms. Controversy exists, however, regarding the precise indications for and efficacy of these heterologous serum products.<sup>126,128–131</sup> Administration is reasonable in cases of severe envenomation, especially in children not responding promptly to the preceding conservative measures. These antivenoms do carry some risk of anaphylactoid reactions and delayed serum sickness, and their administration should be with similar precautions as outlined previously for snake and spider antivenoms.

Adults stung by potentially dangerous scorpions should be observed for 4 to 6 hours. If significant toxicity appears, they should be admitted to an appropriate hospital unit. If systemic signs and symptoms are absent after several hours of observation, they may be discharged with aftercare instructions to return if they get worse. Owing to the increased severity of envenomations in small children, symptomatic cases and all infants should be admitted to an intensive care setting and monitored closely.<sup>105,125,132</sup>

## MISCELLANEOUS VENOMOUS ARTHROPODS

An exhaustive description of all venomous or harmful arthropods is beyond the scope of this chapter. Examples of other arthropods that can cause significant envenomation in humans include centipedes and the larval forms (caterpillars) of the order Lepidoptera (moths and butterflies). The vast majority of bites or stings by these miscellaneous creatures and by unidentified arthropods can be treated satisfactorily with sound supportive care, including local cooling of the wound, elevation and splinting of the involved extremity, updating the tetanus status as necessary, and administering appropriate analgesics. In the rare case of hypotension, IV crystalloid fluids should be initially administered, followed by vasopressor agents if there is a lack of response to volume repletion. If there is concern for an anaphylactic response to the venom, this should be managed as outlined previously under the discussion on Hymenoptera. Wound care should focus on regular cleaning of wounds, removal of any retained foreign bodies (stingers, hairs, spines, etc.), and judicious debridement of clearly necrotic tissue. If secondary infection occurs, appropriate broad-spectrum antibiotics should be administered depending on the clinical scenario. If systemic toxicity is evident, then routine laboratory tests should be obtained (complete blood count, serum electrolytes, renal and liver function studies, blood glucose, coagulation studies,

and urinalysis). Depending on the severity of the poisoning and the underlying health of the victim, a chest radiograph and electrocardiogram may be useful.

## ■ Marine Envenomations

Ocean-dwelling organisms have developed unique methods of self-defense, and as humans increase their exposure to the marine environment, the possibility of hazardous encounters also increases. It is important that health care providers be familiar with the unique dangers of the aquatic environment, especially the presentation and management of poisonous bites and stings. Most cases of marine venom poisoning occur as acts of self-defense on the part of the creatures and rarely occur without provocation.<sup>133,134</sup>

Stinging invertebrates are among the most common and dangerous marine animals. These organisms envenom by means of dischargeable, stinging, venom-laden barbs contained in organelles known as nematocysts.<sup>135</sup> Millions of microscopic venom-bearing stinging cells (nematocytes) cover the surfaces of the tentacles and are triggered chemically or by tactile stimulation. Venom has direct and indirect effects on the vascular and autonomic nervous systems. Centrally mediated respiratory depression and/or anaphylaxis may occur.<sup>135–137</sup>

Stinging vertebrates typically introduce their venoms to humans via the specialized glands associated with sharp spines, which may be present on their gill covers or dorsal, pectoral, or anal fins. Injuries caused by these animals commonly involve puncture wounds, which may be quite traumatic, in addition to the envenomation. Envenomation syndromes caused by this diverse group of marine animals include sudden cardiogenic death, tissue necrosis, paralysis, anaphylaxis, and a range of enigmatic symptoms and signs specific to the individual animal.<sup>138–150</sup> Venom composition varies among species, but in general has been shown to have a destabilizing effect on cell membranes, in some cases mediated by effects on ion channels.

## ENVENOMATIONS BY MARINE INVERTEBRATES

### Sponges

Two general syndromes are induced by contact with sponges. The first is a pruritic dermatitis similar to plant-induced allergic dermatitis. A typical offender is the friable Hawaiian or West Indian fire sponge (*Tedania ignis*).<sup>133,151</sup> Within a few hours, but sometimes within 10 to 20 minutes, after skin contact, the victim suffers itching and burning, which may progress to local joint swelling, soft tissue edema, vesiculation, and stiffness, particularly if small pieces of broken sponge are retained in the skin near the interphalangeal or metacarpophalangeal joints. Abraded skin, such as that which has been scraped on stony coral, may allow more rapid or greater absorption of toxin(s).<sup>152</sup> Untreated, mild reactions subside within 3 to 7 days.<sup>153</sup> When large skin areas are involved, the victim may complain of fever, chills, malaise, dizziness, nausea, muscle cramps, and formication. Systemic erythema multiforme or an anaphylactoid reaction may develop a week to 14 days after a severe exposure.<sup>154</sup> The skin

may become mottled or purpuric, occasionally after a delay of up to 10 days.<sup>155</sup> The second syndrome is irritant dermatitis that follows penetration of small spicules of silica or calcium carbonate into the skin. In severe cases, surface desquamation of the skin may follow in 10 days to 2 months. No medical intervention can retard this process. Recurrent eczema and persistent arthralgias are rare complications.

To treat, the skin should be gently dried. Spicules should be removed, if possible, using adhesive tape, a thin layer of rubber cement, or a facial peel. As soon as possible, dilute (5%) acetic acid (vinegar) soaks for 10 to 30 minutes three or four times a day should be applied to all affected areas.<sup>133,136,156</sup> Isopropyl alcohol 40% to 70% is a reasonable second choice. Erythema multiforme may require the administration of a systemic glucocorticoid, beginning with a moderately high dose (prednisone 60–100 mg), tapered over 2 to 3 weeks. After the initial decontamination, a mild emollient cream or steroid preparation may be applied to the skin. If the allergic component is severe, particularly if there is weeping, crusting, and vesiculation, a systemic glucocorticoid (prednisone 60–100 mg, tapered over 2 weeks) may be beneficial.

### Coelenterates (Cnidaria)

Coelenterates are an enormous group, comprising approximately 10,000 species, at least 100 of which are dangerous to humans. Coelenterates that possess the venom-charged stinging cells are known as cnidaria (nettle). For practical purposes, the cnidaria can be divided into (1) hydrozoans, such as the Portuguese man-of-war; (2) scyphozoans, such as true jellyfish; and (3) anthozoans, such as soft corals, stony corals, and anemones. Fenner divides jellyfishes into three main classes: schyphozoans (true jellyfishes), with tentacles arising at regular intervals around the bell; cubozoans (e.g., “box” jellyfishes), with tentacles arising only from the corners—these may be further divided into carybdeids (e.g., Irukandji), with only one tentacle (except in rare cases) arising from each lower corner of the bell, and chirodropids, which have more than one tentacle in each corner of the bell; and other jellyfishes, such as the hydrozoans (e.g., *Physalia* species).

### Clinical Aspects

For clinical purposes, a considerable phylogenetic relationship exists among all stinging species, so that the clinical features of the coelenterate syndrome are fairly constant, with a spectrum of severity. The wise clinician suspects a coelenterate envenomation in all unexplained cases of collapse in the surf, diving accidents, and near drownings. Any victim in distress pulled from marine waters should be carefully examined for one or more cutaneous lesions that may provide the clue to a coelenterate envenomation.

**Mild Envenomation.** There is usually an immediate pricking or stinging sensation, accompanied by pruritus, paresthesias, burning, throbbing, and radiation of the pain centrally from the extremities to the groin, abdomen, and axillae. The area involved by the nematocysts becomes red-brown-purple, often in a linear whiplike fashion, corresponding to tentacle prints. Other features are blistering, local edema angioedema

and wheal formation, as well as violaceous petechial hemorrhages. The papular inflammatory skin rash is strictly confined to the areas of contact and may persist for up to 10 days. If the envenomation is slightly more severe, the aforementioned symptoms, which are evident in the first few hours, can progress over a course of days to local necrosis, skin ulceration, and secondary infection. Untreated, the minor-to-moderate skin disorder resolves over 1 to 2 weeks, with occasional residual hyperpigmentation for 1 to 2 months. Rubbing can cause lichenification. Local hyperhidrosis, fat atrophy, and contracture may occur.<sup>157</sup> Permanent scarring or keloids may result. It has been suggested that sensitization may occur without a definite history of a previous sting, since coelenterates may release antigenic and allergenic venom components into the water.

**Moderate and Severe Envenomation.** The skin manifestations are similar or intensified and compounded by the onset of systemic symptoms, which may appear immediately or be delayed by several hours:

1. Neurologic: malaise, headache, aphonia, diminished touch and temperature sensation, vertigo, ataxia, spastic or flaccid paralysis, mononeuritis multiplex, Guillain-Barré syndrome, parasympathetic dysautonomia, plexopathy, radial-ulnar-median nerve palsies, brainstem infarction (not a confirmed relationship), delirium, loss of consciousness, convulsions, coma, and death<sup>158–161</sup>
2. Cardiovascular: anaphylaxis, hemolysis, hypotension, small artery spasm, bradyarrhythmias (including electromechanical dissociation and asystole), tachyarrhythmias, vascular spasm, deep venous thrombosis, congestive heart failure, and ventricular fibrillation
3. Respiratory: rhinitis, bronchospasm, laryngeal edema, dyspnea, cyanosis, pulmonary edema, and respiratory failure
4. Musculoskeletal or rheumatologic: abdominal rigidity, diffuse myalgia and muscle cramps, muscle spasm, fat atrophy, arthralgias, reactive arthritis (sero-negative symmetric synovitis with pitting edema),<sup>162</sup> and thoracolumbar pain
5. Gastrointestinal: nausea, vomiting, diarrhea, dysphagia, hypersalivation, and thirst
6. Ocular: conjunctivitis, chemosis, corneal ulcers, corneal epithelial edema, keratitis, iridocyclitis, elevated intraocular pressure, synechiae, iris depigmentation, chronic unilateral glaucoma, and lacrimation<sup>163,164</sup>
7. Other: acute renal failure, lymphadenopathy, chills, fever, and nightmares

**Treatment.** Therapy is directed at stabilizing major systemic decompensation, opposing the venom's multiple effects, and alleviating pain. Generally, only severe *Physalia* or Cubomedusae stings result in rapid decompensation, unless anaphylaxis is present. Hypotension should be managed with the prompt intravenous administration of crystalloid, such as lactated Ringer's solution. This must be done in concert with detoxification of any nematocysts that are still attached to the victim, to limit the perpetuation of envenomation. Any victim with a systemic component should be observed for a period of at least 6 to 8 hours because rebound phenomena after

successful treatment are not uncommon. All elderly victims should undergo electrocardiography and be observed on a cardiac monitor, with frequent checks for arrhythmias. Urinalysis demonstrates the presence or absence of hemoglobinuria, indicating hemolysis.<sup>165</sup> If this is the case, the urine should be alkalinized with bicarbonate to prevent the precipitation of pigment in the renal tubules, while a moderate diuresis (30 to 50 mL/hr) is maintained with a loop diuretic (such as furosemide or bumetanide) or mannitol (0.25 g/kg intravenously every 8 to 12 hours). If there are signs of distal ischemia or an impending compartment syndrome, standard diagnostic and therapeutic measures apply. Vasospasm associated with jellyfish envenomation may be severe, prolonged, and refractory to regional sympathectomy and intra-arterial reserpine or pentoxifylline.<sup>166</sup> *Chironex fleckeri*, the box jellyfish, produces the only coelenterate venom for which specific antivenom exists.

**Treatment of Dermatitis.** If a person is stung by a coelenterate, the following steps should be taken:

1. Immediately rinse the wound with seawater, not with fresh water. Do not rub the wound with a towel or clothing to remove adherent tentacles. Surf life-savers (lifeguards) in the United States and Hawaii have mentioned that a freshwater hot shower applied with a forceful stream may decrease the pain of an envenomation. If this is successful, one theoretical explanation is that the mechanical effect of the water stream (that dislodges tentacle fragments and/or stinging cells) supercedes the deleterious (sting-stimulating) effect of the hypotonic water. Remove any gross tentacles with forceps or a well-gloved hand. In an emergency, the keratinized palm of the hand is relatively protected, but take care not to become envenomed.
2. Commercial (chemical) cold or ice packs applied over a thin dry cloth or plastic membrane have been shown to be effective when applied to mild or moderate *Physalia utriculus* ("bluebottle") stings.<sup>167</sup> Whether the melt-water from ice applied directly to the skin can stimulate the discharge of nematocysts has not been determined. Applications of hot packs or gentle rinses with hot water are not recommended.
3. Acetic acid 5% (vinegar) is the treatment of choice to inactivate *Chironex fleckeri* toxin. Vinegar will not alleviate the pain from a *Chironex* sting but interrupts the envenomation. The detoxicant should be applied continuously for at least 30 minutes or until the pain is relieved. A sting from the Australian *Physalia physalis*, a relatively recently differentiated species, should not be doused with vinegar, as this may cause discharge of up to 30% of nematocysts.<sup>149</sup>
4. For a sting from *Chironex fleckeri*, the pressure-immobilization technique for venom sequestration is sometimes recommended. If vinegar is immediately available, a liberal dousing should occur and at least 30 seconds should pass before removing the tentacles. After the tentacles are removed, proceed at once with pressure-immobilization. If vinegar is unavailable, remove the tentacles before applying pressure-immobilization.<sup>168</sup> A venolymphatic occlusive tourniquet should be considered only if a topical detoxicant and pressure-immobilization are unavailable, the victim suffers from a severe systemic reaction, and

transport to definitive care is delayed. *Chironex* antivenom should be administered intravenously as soon as possible. The intramuscular route is less preferred. The antivenom is supplied in ampoules of 20,000 units by Commonwealth Serum Laboratories, Melbourne, Australia. The initial dose is one ampoule (diluted 1:5 to 1:10 in isotonic crystalloid; dilution with water is not recommended) administered intravenously over 5 minutes, or three ampoules intramuscularly. This has been administered successfully over the years by members of the Queensland Surf Life-Saving Association and the Queensland Ambulance Transport Brigade. Although the antivenom is prepared by hyperimmunizing sheep and adverse reactions reported to date have been rare and mild, the prudent physician is always prepared to treat anaphylaxis or serum sickness.<sup>169</sup> It cannot be overemphasized that the timely administration of antivenom can be lifesaving.<sup>170</sup> In addition to its lifesaving properties, the early administration of antivenom may markedly reduce pain and decrease subsequent skin scarring.<sup>171</sup> Antivenom administration may be repeated once or twice every 2 to 4 hours until there is no further worsening of the skin discoloration, pain, or systemic effects.

For stings from other species, there are substances that may be more specific and, therefore, more effective. Depending on the species, these include isopropyl alcohol (40% to 70%), dilute ammonium hydroxide, sodium bicarbonate (particularly for stings of the sea nettle *Chrysaora quinquecirrha*), olive oil, sugar, urine, and papain (papaya latex [juice] or unseasoned meat tenderizer powdered or in solution). Perfume, aftershave lotion, and high-proof liquor are not particularly efficacious and may be detrimental, as are formalin, ether, and gasoline.

1. Once the wound has been soaked with a decontaminant (e.g., vinegar), remaining (and often "invisible") nematocysts must be removed. The easiest way to do this is to apply shaving cream or a paste of baking soda, flour, or talc and to shave the area with a razor or similar tool. If sophisticated facilities are not available, the nematocysts should be removed by making a sand or mud paste with seawater and using this to help scrape the victim's skin with a sharp-edged shell or piece of wood.
2. A topical anesthetic ointment (lidocaine, 2.5%) or spray (benzocaine, 14%), antihistaminic cream (diphenhydramine or tripeleminamine), or mild steroid lotion (hydrocortisone, 1%) may be soothing. These are used after the toxin is inactivated.
3. Victims should receive standard antitetanus prophylaxis. Each wound should be checked at 3 and 7 days after injury for infection. Any ulcerating lesion should be cleaned three times a day and covered with a thin layer of nonsensitizing antiseptic ointment, such as mupirocin.

**Prevention.** A protocol has been developed to establish the effectiveness of topical agents to block firing of nematocysts.<sup>172</sup> Current research is directed at a combination jellyfish sting inhibitor-sunscreen lotion (Safe Sea: [www.nidaria.com](http://www.nidaria.com)) that may prevent discharge of more than 90% of nematocysts that contact protected skin.<sup>173</sup> Failed topical barriers include petrolatum, mineral oil, silicone ointment, cocoa butter, and mechanic's grease.

## Seabather's Eruption

Seabather's eruption, commonly termed *sea lice* ("pika-pika" around the Belize barrier reef; "sea poisoning," "sea critters," and "ocean itch" are other names), refers to a dermatitis that results from contact with ocean water.<sup>174</sup> It predominantly involves covered areas of the body and is commonly caused by pinhead-sized (0.5 mm) greenish-brown to black larvae of the thimble jellyfish *Linuche unguiculata*, which breeds in Caribbean waters throughout the summer with a peak in May. A swimmer who encounters the stinging forms usually complains of cutaneous discomfort soon after contact, often while in the water or soon after exiting. The eruption occurs a few minutes to 12 hours after bathing and consists of erythematous and intensely pruritic wheals, vesicles, or papules that persist for 2 to 14 days and then involute spontaneously (Plate 9-4A). When a bathing suit has been worn by a woman, the areas commonly involved include the buttocks, genital region, and breasts. A person at the water's surface (commonly a person who surfaces after a dive) may suffer stings to the exposed neck, particularly if there has been recent motorboat activity in the vicinity, which may disturb and fragment the causative jellyfish. Nematocysts adherent to scalp hair may sting the neck as the hair hangs down. Coalescence indicates a large inoculum. Individual lesions resemble insect bites. Surfers develop lesions on areas that contact the surfboard (chest and anterior abdomen). The rash may also be seen under bathing caps and swim fins or along the edge of the cuffs of wet suits, T-shirts, or "stinger suits."<sup>175</sup> Field management is identical to that for any coelenterate sting (see preceding discussion), with the empirical observation that topical papain may be slightly more effective as an initial decontaminant than vinegar, isopropyl alcohol, or other substances. Substances that are felt to be ineffective include hydrogen peroxide, garlic, antifungal spray, anti-head lice medication, petroleum distillates, fingernail polish, and citrus juice. Further treatment is palliative and consists of calamine lotion with 1% menthol. Because the lesions rarely extend into the dermis, a potent topical corticosteroid may be helpful in mild cases, but benefit is not invariably attained. In a more severe case, an oral or parenteral antihistamine or systemic corticosteroid may be used.

## Starfish

Starfish are covered with thorny spines of calcium carbonate crystals held erect by muscle tissue. Glandular tissue interspersed in or underneath the epidermis (integument) produces a slimy venomous substance. The ice pick–like spine of *Acanthaster planci* (Plate 9-4B) can penetrate the hardest of diving gloves. As the spine enters the skin, it carries venom into the wound, with immediate pain, copious bleeding, and mild edema. The pain is generally moderate and self-limited, with remission over a period of 30 minutes to 3 hours. The wound may become dusky or discolored. Multiple puncture wounds may result in acute systemic reactions, including paresthesias, nausea, vomiting, lymphadenopathy, and muscular paralysis. The wound should immediately be immersed in nonscalding hot water to tolerance (113°F or 45°C) for 30 to 90 minutes or until there is significant pain relief. The pain is rarely severe enough to require local anesthetic infiltration.

The puncture wound should be irrigated and explored to remove all foreign material. Because of the stout nature of the spines, it is rare to retain a fragment. However, if any question of a foreign body exists, a soft tissue radiograph often identifies the fractured spine.

## Sea Urchins

The venom apparatuses of sea urchins consist of the hollow, venom-filled spines and the triple-jawed globiferous pedicellariae. Venom may also be released from within a thin integumentary sheath on the external surface of the spines of certain urchins (Plate 9-4C).

Urchins may be extremely dangerous to handle; the spines, which are attached to the shell with a modified ball-and-socket joint, are brittle and break off easily in the flesh, lodging deeply and making removal difficult. Pedicellariae are small, delicate seizing organs attached to the stalks scattered among the spines. These are considered to be modified spines with flexible heads.<sup>152</sup> Globiferous pedicellariae are typified by those found in *Toxopneustes pileolus* (flower urchin).

Venomous spines inflict immediate and intensely painful stings. The pain is initially characterized by burning, which rapidly evolves into severe local muscle aching with visible erythema and swelling of the skin surrounding the puncture site or sites. Frequently a spine breaks off and lodges in the victim. Some sea urchin spines contain purplish dye, which may give a false impression of spines left in the skin. Soft tissue density x-ray techniques or magnetic resonance imaging may reveal a radiopaque foreign body. If a spine enters a joint, it may rapidly induce severe synovitis. If multiple spines have penetrated the skin, particularly if they are deeply embedded, systemic symptoms may rapidly develop, including nausea, vomiting, paresthesias, numbness and muscular paralysis, abdominal pain, syncope, hypotension, and respiratory distress. The stings of pedicellariae are often of greater magnitude. Secondary infections and indolent ulceration are common. A delayed hypersensitivity-type reaction ("flare-up") at the site of the puncture(s) has been described, in which the victim demonstrates erythema and pruritus in a delayed fashion (7 to 10 days) post primary resolution from the initial envenomation.<sup>176</sup>

The envenomed body part should immediately be immersed in nonscalding hot water (upper limit 113°F or 45°C) to tolerance for 30 to 90 minutes in an attempt to relieve pain. Any pedicellariae still attached to the skin must be removed or envenomation will continue. This may be accomplished by applying shaving foam and gently scraping with a razor. Embedded spines should be removed with care because they easily fracture. Black or purplish discoloration surrounding the wound after spine removal is often merely spine dye. Although some thin venomous spines may be absorbed within 24 hours to 3 weeks, it is best to remove those that are easily reached. All thick calcium carbonate spines should be removed because of the risk of infection, foreign body encasement granuloma, or dermoid inclusion cyst. External percussion to achieve fragmentation may prove disastrous if a chronic inflammatory process is initiated in sensitive tissue of the hand or foot. If the spines have acutely entered joints or are closely aligned to neurovascular structures, the surgeon should take advantage of an operating

microscope in an appropriate setting to remove all spine fragments. If the spine has entered an interphalangeal joint, the finger should be splinted until the spine is removed to limit fragmentation and further penetration. Infections are common, and deep puncture wounds are an indication for prophylactic antibiotics.

### Cone Snails (“Cone Shells”)

Most harmful cone snails (“cones”) are creatures of shallow Indo-Pacific waters; they are predators that feed by injecting rapid-acting venom by means of a detachable, dartlike radular tooth. Most stings occur on the fingers and hand, as the unknowledgeable fossicker incorrectly handles a hazardous specimen. Mild envenomations resemble bee or wasp stings. The initial pain is followed by localized ischemia, cyanosis, and numbness in the area surrounding the wound. More serious envenomations induce paresthesias at the wound site, which rapidly encompass the limb and then become perioral prior to generalized. Partial paralysis transitions to generalized muscular paralysis causing diaphragmatic dysfunction and respiratory failure. Coma has been observed, and death is attributed to diaphragmatic paralysis or cardiac failure. Other symptoms include dysphagia, syncope, weakness, failing coordination, areflexia, aphonia, dysarthria, diplopia, ptosis, absent gag reflex, blurred vision, and pruritus.

No antivenom is available for cone shell envenomation. The pressure-immobilization technique makes sense and should be applied. Cardiovascular and respiratory support are the usual priorities after a severe envenomation. Edrophonium (10 mg intravenously in an adult) has been suggested as empirical therapy for paralysis. Adverse reactions to edrophonium (anticholinesterase inhibitor) include salivation, nausea, diarrhea, and muscle fasciculations. These can be ameliorated with atropine 0.6 mg IV.

### Octopuses

Octopus bites are rare but can result in severe envenomations. Fatalities have been reported from the bites of the Australian blue-ringed (or “spotted”) octopuses, *Octopus (Hapalochlaena) maculosus* and *O. (H.) lunulata*. These small creatures, which rarely exceed 20 cm in length with tentacles extended, are found throughout the Indo-Pacific in rock pools, under discarded objects and shells, and in shallow waters.<sup>177</sup>

The venom of *H. maculosa* contains at least one fraction identical to tetrodotoxin, which blocks peripheral nerve conduction by interfering with sodium conductance in excitable membranes.<sup>178</sup> This paralytic agent rapidly produces neuromuscular blockade, notably of the phrenic nerve supply to the diaphragm.

Most victims are bitten on the hand or arm, as they handle the creature.<sup>179</sup> An octopus bite usually consists of two small puncture wounds. The bite goes unnoticed or causes only a small amount of discomfort, described as a minor ache, slight stinging, or a pulsating sensation. Occasionally the site is initially numb, followed in 5 to 10 minutes by discomfort that may spread to involve the entire limb, persisting for up to 6 hours. Within 30 minutes, considerable erythema, swelling, tenderness, heat, and pruritus may develop. By far the most

common local tissue reaction is absence of symptoms, a small spot of blood, or a tiny blanched area.<sup>180</sup> More serious symptoms are related predominantly to the neurotoxic properties of the venom. Within 10 to 15 minutes of the bite, the patient notices oral and facial numbness, rapidly followed by systemic progression.<sup>179</sup> Voluntary and involuntary muscles are involved, and the illness may rapidly progress to total flaccid paralysis and respiratory failure. Other symptoms include perioral and intraoral anesthesia (classically, numbness of the lips and tongue), diplopia, blurred vision, aphonia, dysphagia, ataxia, myoclonus, weakness, a sense of detachment, nausea, vomiting, peripheral neuropathy, flaccid muscular paralysis, and respiratory failure, which may lead to death.

First aid at the scene might include the pressure-immobilization technique, although this is as yet unproven for management of octopus bites. Prompt mechanical respiratory assistance has by far the greatest influence on the outcome. Respiratory demise should be anticipated early, and the rescuer should be prepared to provide artificial ventilation, including endotracheal intubation and the application of a mechanical ventilator. The duration of intense clinical venom effect is 4 to 10 hours, after which the victim who has not suffered an episode of significant hypoxia shows rapid signs of improvement. Complete recovery may require 2 to 4 days.

## ENVENOMATIONS BY MARINE VERTEBRATES

### Stingrays

Stingrays (Plate 9-4D) are usually found in tropical, subtropical, and warm temperate oceans, generally in shallow (intertidal) water areas, such as sheltered bays, shoal lagoons, river mouths, and sandy areas between patch reefs.<sup>181</sup> Rays can enter brackish and fresh waters as well. The venom apparatus of stingrays consists of a bilaterally retroserrate spine or spines and the enveloping integumentary sheath or sheaths. The elongate and tapered vasodentine spine is firmly attached to the dorsum of the tail (whip) by dense collagenous tissue and is edged on either side by a series of sharp retrorse teeth. Along either edge on the underside of the spine are the two ventrolateral glandular grooves, which house the soft venom glands. The entire spine is encased by the integumentary sheath, which also contains some glandular cells. The sting is often covered with a film of venom and mucus.

Stingray “attacks” are purely defensive gestures that occur when an unwary human handles, corners, or steps on a camouflaged creature while wading in shallow waters. The tail of the ray reflexively whips upward and accurately thrusts the caudal spine or spines into the victim, producing a puncture wound or jagged laceration. The integumentary sheath covering the spine is ruptured and venom is released into the wound, along with mucus, pieces of the sheath, and fragments of the spine.

The pain may radiate centrally, peaks at 30 to 60 minutes, and may last for up to 48 hours. The wound is initially dusky or cyanotic and rapidly progresses to erythema and hemorrhagic discoloration, with rapid fat and muscle hemorrhage and necrosis.<sup>182</sup> If discoloration around the wound edge is not immediately apparent, within 2 hours it often extends

several centimeters from the wound. Systemic manifestations include weakness, nausea, vomiting, diarrhea, diaphoresis, vertigo, tachycardia, headache, syncope, seizures, inguinal or axillary pain, muscle cramps, fasciculations, generalized edema (with truncal wounds), paralysis, hypotension, arrhythmias, and death.<sup>183,184</sup>

Treatment is directed at combating the effects of the venom, alleviating pain, and preventing infection. If hot water for immersion and irrigation is not immediately available, the wound should be irrigated immediately with nonheated water or saline. If sterile saline or water is not available, tap water may be used. This removes some venom and mucus, and may provide minimal pain relief.

As soon as possible, the wound should be soaked in non-scalding hot water to tolerance (upper limit 113°F or 45°C) for 30 to 90 minutes. During the hot water soak (or at any time, if soaking is not an option), the wound should be explored and debrided of any readily visible pieces of the sting or its integumentary sheath, which would continue to envenom the victim. Cryotherapy can be disastrous. One local remedy, application of half a bulb of onion directly to the wound, has been reported to decrease the pain and perhaps inhibit infection following a sting from the blue-spotted stingray *Dasyatis kuhlii*.<sup>185</sup>

Pain control should be initiated during the first debridement or soaking period. Narcotics may be necessary. Local infiltration of the wound with 1% to 2% lidocaine (Xylocaine) or bupivacaine 0.25% (not to exceed 3–4 mg/kg total dose in adults; not approved in children under the age of 12 years) without epinephrine may be useful. A regional nerve block may be necessary.

After the soaking procedure, the wound should be prepared in a sterile fashion, reexplored, and thoroughly debrided. Wounds should be packed open for delayed primary closure or sutured loosely around adequate drainage in preference to tight closure, which might increase likelihood of wound infection. Another approach that has been mentioned is wound excision followed by packing with an alginate-based wick dressing.<sup>186,187</sup> Prophylactic antibiotics appropriate to cover, among other organisms, the genus *Vibrio* are recommended because of the high incidence of ulceration, necrosis, and infection.

## Scorpionfish

Scorpionfish are divided into three groups typified by different genera on the basis of venom organ structure: (1) *Pterois* (zebrafish, lionfish [Plate 9-4E], and butterfly cod), (2) *Scorpaena* (scorpionfish [Plate 9-4F], bullrout, and sculpin), and (3) *Synanceja* (stonefish [Plate 9-4G]). The venom organs are the 12 or 13 (of 18) dorsal, 2 pelvic, and 3 anal spines, with associated venom glands. Although they are frequently large, plumelike, and ornate, the pectoral spines are not associated with venom glands. Each spine is covered with an integumentary sheath, under which venom filters along grooves in the anterolateral region of the spine from the paired glands situated at the base or in the midportion of the spine.

*Pterois* species carry long, slender spines with small venom glands covered by a thin integumentary sheath. *Scorpaena* species carry longer, heavy spines with moderate-sized venom

glands covered by a thicker integumentary sheath. *Synanceja* species carry short, thick spines with large, well-developed venom glands covered by an extremely thick integumentary sheath.

Pain is immediate and intense, with radiation centrally. Untreated, the pain peaks at 60 to 90 minutes and persists for 6 to 12 hours. With a stonefish envenomation, the pain may be severe enough to cause delirium and may persist at high levels for days. The wound and surrounding area are initially ischemic and then cyanotic, with more broadly surrounding areas of erythema, edema, and warmth. Vesicles may form. Rapid tissue sloughing and close surrounding areas of cellulitis, with anesthesia adjacent to peripheral hypesthesia, may be present within 48 hours. Systemic effects include anxiety, headache, tremors, maculopapular skin rash, nausea, vomiting, diarrhea, abdominal pain, diaphoresis, pallor, restlessness, delirium, seizures, limb paralysis, peripheral neuritis or neuropathy, lymphangitis, arthritis, fever, hypertension, respiratory distress, bradycardia, tachycardia, atrioventricular block, ventricular fibrillation, congestive heart failure, pericarditis, hypotension, syncope, and death.<sup>188</sup> The wound is indolent and may require months to heal, only to leave a cutaneous granuloma or marked tissue defect, particularly after a secondary infection or deep abscess. Mild pain may persist for days to weeks.

As soon as possible, the wound or wounds should be immersed in nonscalding hot (upper limit 113°F or 45°C) water to tolerance for up to 90 minutes. Recurrent pain that develops after an interval of 1 to 2 hours may respond to repeat hot water treatment. As soon as is practical, all obvious pieces of spine and sheath fragments should be gently removed from the wound. Vigorous irrigation should be performed with warmed sterile saline to remove any integument or slime. If pain is severe or inadequately controlled (in terms of degree or rapidity of relief) by hot water immersion, local tissue infiltration with 1% to 2% lidocaine without epinephrine, or regional nerve block with an anesthetic such as 0.25% bupivacaine, may be necessary.

Although the spine rarely breaks off in the skin, the wound should be explored to remove any spine fragments, which will otherwise continue to envenom and act as foreign bodies, perpetuating an infection risk and poorly healing wound.

Stonefish antivenom is manufactured by the Commonwealth Serum Laboratories, Melbourne, Australia. In cases of severe systemic reactions from stings of *Synanceja* species, and rarely from other scorpionfish, it is administered intramuscularly. As a rough estimate, one ampoule should neutralize one or two significant stings (punctures).

## Sea Snakes

See the previous section on Venomous Snakes.

## CONCLUSION

In view of the thousands of species of venomous animals that inhabit this planet, it is testimony to the tolerance of most of these creatures that venom poisoning does not take a greater toll on humanity. While there are specific interventional measures of benefit for some forms of envenomations, such as antivenom for snakebite or hot water immersion for stingray

stings, it is often the treating physician's ability to anticipate clinical findings and intervene with sound supportive care that ultimately determines the outcome for the victim.

## Plant Toxins in the Tropics

JAMES L. LARSON  
RICHARD F. CLARK

### INTRODUCTION

The study of plant poisoning is termed *phytotoxicology*. This field has not achieved clinical sophistication, in part due to a lack of collaboration between botanists and physicians. Few people possess adequate training in both of these fields. The result has been many poorly documented case reports of plant-related toxicity, often with improper plant identification, using local or common names, and a tendency to combine scientific facts with older fictional accounts.

One of the most significant problems associated with toxic plant exposures is plant identification. Plant toxicity seems to occur consistently on a genus level, although species variation may alter toxicity. Seasonal variations in toxin content, cross-breeding, and changing environmental conditions can all affect toxic potential. Trained botanists often require plant specimens for adequate confirmation of a local species. In addition, the nomenclature of many plant species varies greatly in different regions, making identification more difficult. Common names are often misleading. “Nightshade,” for instance, is a name frequently associated with “deadly nightshade” or *Atropa belladonna*. However, the nightshade family, Solanaceae, also includes the edible potato and the poisonous Jerusalem cherry (*Solanum pseudocapsicum*).

Exposures to potentially poisonous plants are common, accounting for an estimated 5% to 10% of all calls to poison control centers. Fortunately, houseplant ingestions result in the majority of these calls, and morbidity and mortality following these incidents are low. Throughout history, the toxic properties of many plants have been described. Information on individual plant toxicity is enormous and constantly expanding. Some plants, such as hemlock, are known to be rapidly fatal when taken in sufficient quantities. Most, however, have not been studied sufficiently. Tropical and subtropical environments harbor numerous species that lack clinical data regarding toxicity.

This chapter covers some of the more common and most toxic species of plants encountered in tropical and subtropical environments (Table 10-1). Identification, pathophysiology, and therapeutic considerations are discussed.

### GENERAL MANAGEMENT

#### History

There is no more important tool in the successful management of plant ingestion than obtaining an accurate history.

Timing of the exposure and onset of toxicity, the plant portion and amount ingested, and a description of symptoms are essential to beginning the evaluation. An account of the preparation of the plant or fruit should be obtained. The time of year and seasonal weather conditions should be noted. Potential exposures to other people should be explored.

In order to facilitate identification, portions of the suspected plant should be gathered and brought to the health care facility. Books are often available at emergency departments or through poison control centers and can be used to match common with taxonomic names. If necessary, toxicologists, botanists, or mycologists can often be located through poison centers or local universities.

### Physical Examination

Frequently, the health care provider must initiate treatment before reliable identification of the ingested plant can be made. Poisonings by some plant species often present with characteristic physical examination findings (Box 10-1). The most common manifestation of plant toxicity after ingestion is gastroenteritis. Nausea and vomiting can be severe after exposure to numerous plants and can necessitate intravenous fluid repletion. Dehydration with electrolyte imbalance is the main concern following these ingestions. Ricin- and abrin-containing plants (*Ricinus communis* and *Abrus precatoris*) and poke-weed (*Phytolacca americana*) are examples of this type of toxicity. *Philodendron* and other Araceae are also capable of causing gastrointestinal irritation due to the presence of calcium oxalate crystals or other substances within their leaves and stems.

Several classes of plants are known for cardiovascular toxicity. Numerous species of oleander (*Nerium oleander* and *Thevetia peruviana*), foxglove (*Digitalis purpurea*), lily of the valley (*Convallaria majalis*), and red squill (*Urgenia maritima*) all contain cardiac glycosides and can predispose to ventricular dysrhythmias and heart block in severe cases. *Veratrum* and *Rhododendron* species contain toxins that can lead to hypotension and bradycardia. *Aconitum* species, commonly sold as herbal remedies, can impair ion movement through myocyte cell membranes leading to life-threatening dysrhythmias.

Severe neurotoxicity is an uncommon but potentially lethal manifestation of plant poisoning. Water hemlock (*Cicuta* spp.) is responsible for most plant-related fatalities in the United States and can cause refractory status epilepticus after ingestion. Others, such as moonseed (*Menispermum canadense*) and chinaberry (*Melia azedarach*), contain neurotoxic components, but documented cases of neurotoxicity after ingestion are rare. Many plants can produce an altered level of consciousness. *Datura* species such as jimsonweed, deadly nightshade (*Atropa belladonna*), and angels' trumpet (*Brugmansia* spp.) are just a few that contain atropine, scopolamine, and hyoscyamine. Ingestion of the leaves, seeds, or teas made from the seeds of these species produces the classic findings of antimuscarinic toxicity, including dry mouth and skin, hallucinations, tachycardia, urinary retention, and ileus. Others in the tobacco family (*Nicotiana* and *Lobelia* spp.) and poison hemlock (*Conium maculatum*) cause nicotinic receptor stimulation when ingested, resulting in nausea, vomiting, seizures, and paralysis in severe cases.

**Table 10-1 Commonly Encountered Toxic Plants**

Common Name	Scientific Name	Toxic Parts	Poisonous Principles	Symptoms
Akee	<i>Blighia sapida</i>	Fruit	Hypoglycin A	Jamaican vomiting sickness occurs from eating unripe fruit; toxin inhibits gluconeogenesis, leading to profound hypoglycemia; classic symptoms with diaphoresis, nausea, and vomiting, progressing to seizures and coma; much more common in children
Apricot, apple, peach, pear	<i>Prunus</i> spp.	Seeds	Amygdalin glycosides	Seeds need to be chewed to release amygdalin that is converted to cyanide by stomach acid; classic symptoms of cyanide poisoning, such as metabolic acidosis, hypotension, coma, and seizures, can occur in large ingestions
Autumn crocus, saffron	<i>Colchicum autumnale</i>	All parts	Colchicine	Pain in mouth, throat, and abdomen; severe nausea, vomiting, and diarrhea; symptoms usually appear 2–6 hr after ingestion; bone marrow depression possible, leading to sepsis or other infections after period free of symptoms; peripheral neuropathy and alopecia possible late complications
Glory lily	<i>Gloriosa superba</i>			Irritant to skin, mouth, and throat; causes gastroenteritis
Beauty of the night, four o'clock	<i>Mirabilis jalapa</i>	Root, seed	The alkaloid trigonelline	
Bird of paradise	<i>Caesalpinia gilliesii</i>	Pods, seeds	Unknown	Severe gastroenteritis, dehydration
Bleeding heart	<i>Dicentra formosa</i>	Foliage, roots	Isoquinoline alkaloids	Tremors, staggering gait, convulsions, tachypnea, salivation, convulsions; death may be due to respiratory insufficiency and paralysis but is mostly reported from animal exposures
Dutchman's breeches	<i>Dicentra cucullaria</i>			Tropical ataxic neuropathy can result from eating fruit; neurologic symptoms include optic atrophy, deafness, and peripheral neuropathy; lower extremity weakness is most common sequela; paralysis may occur
Cassava	<i>Manihot esculenta</i>	Fruit or tuber	Linamarin, a cyanogenic glycoside	
Castor bean	<i>Ricinus communis</i>	All parts, mainly seeds	Ricin and ricinine (toxalbumins)	Severe nausea, vomiting, and diarrhea; burning sensation in mouth and throat; hemolysis of red blood cells; renal insufficiency; death may be associated with dehydration or systemic poisoning with toxalbumins (rare); 1–3 seeds in a child reported to be lethal
Chinaberry	<i>Melia azedarach</i>	Entire plant, especially fruit	Tetranortriterpenoid neurotoxins and other compounds	Has caused serious poisoning in animals (hogs and sheep), including tachypnea, tachycardia, sluggish movements, vomiting; humans develop severe gastroenteritis and weakness; case reports suggest 6–8 fruits may be lethal to a child
Christmas rose	<i>Helleborus niger</i>	Rootstocks and leaves	Glycosides ranunculin, hellebrin, others	Inflammation and numbing sensations in mouth; vomiting, diarrhea, and possible convulsions; may have a digitalis-like effect on heart from cardiac glycosides
Stinking hellbore	<i>Helleborus foetidus</i>			
Lenten rose	<i>Helleborus orientalis</i>			
Daphne	<i>Daphne mezereum</i> and other species	Berries, bark, leaves	Daphnin and resin mezerenic acid	Plant intensely irritating, producing vesication when rubbed on skin; ingestion produces burning sensation in mouth, throat, and abdomen; bloody emesis and diarrhea are reported; renal insufficiency, convulsions, and death are possible; case reports are rare
Dieffenbachia, dumbcane	<i>Dieffenbachia</i> spp.	All parts	Calcium oxalate and raphide crystals	Irritation of mouth, tongue, lips, and throat; if juice gets in eye, it causes marked burning and inflammation; airway obstruction may occur from swelling

Continued

Table 10-1 Commonly Encountered Toxic Plants—Cont'd

Common Name	Scientific Name	Toxic Parts	Poisonous Principles	Symptoms
Djenkol	<i>Pithecellobium jiringa</i>	Seed or bean	Djenkolic acid crystals	Colicky pain in groin and pelvis with nausea, vomiting, and diarrhea; dysuria and hematuria can precede acute renal failure; crystals not always found in urine
Foxglove	<i>Digitalis purpurea</i>	Leaves and seeds	Cardiac glycosides, including digitoxin, digitalin, and digitonin	One of the sources of the drug digitalis; in large amounts the active principles cause heart block and ventricular arrhythmias; symptoms begin with severe gastroenteritis and confusion; may cause seizures and death
Golden chain, laburnum	<i>Laburnum anagyroides</i>	Flowers, leaves, seeds, bark	The quinolizidine alkaloid cytisine	Dysphagia, mydriasis, agitation, incoordination, vomiting, renal insufficiency; convulsions and coma are possible; action may be similar to nicotine
Poison hemlock, spotted hemlock	<i>Conium maculatum</i>	All parts	Piperidine alkaloids coniine, $\gamma$ -coniceine	Resembles nicotine poisoning; gastroenteritis is common along with salivation and urination; weakness may proceed to loss of muscle tone and paralysis; death may occur from respiratory insufficiency
Water hemlock, wild cowbane, wild carrot, false parsley	<i>Cicuta maculata</i> and other species	All parts, mostly the roots	Cicutoxin	Symptoms appear as soon as 15 min after ingestion and include stomach pain, vomiting, salivation, and refractory convulsions; mydriasis and delirium are common; death may occur within 15 min after ingestion of lethal amount
Holly	<i>Ilex</i>	Berries	Illicin or other alkaloids	Nausea, abdominal pain, severe vomiting, and diarrhea
Iris or blue flag	<i>Iris</i> sp.	Leaves and root stalks	Irritating resinous substance	Produces severe but not usually serious gastroenteritis; can also cause dermatitis
Jack-in-the-pulpit	<i>Arisaema triphyllum</i>	Rhizome	Calcium oxalate crystals	Intense irritation of mouth and throat; burning pain; inflammation of larynx (resembles dumbcane)
Jerusalem cherry, nightshade	<i>Solanum pseudocapsicum</i> and other species	Entire plant, especially berries	Solanine and related alkaloids	Headache, abdominal pain, gastroenteritis; convulsions, and coma may occur more commonly in children; respiratory depression rarely reported
Jimson weed, thorn apple	<i>Datura americana</i> and other species	All parts, especially seeds	The solanaceous alkaloids atropine, hyoscyamine, and scopolamine	Antimuscarinic symptoms include dry mouth, urinary retention, tachycardia, blurred vision with mydriasis, delirium, hallucinations; temperature may be elevated due to anhydrosis; convulsions and coma are possible; handling leaves or seeds followed by rubbing eyes can cause mydriasis
Lantana	<i>Lantana camara</i>	Berries, leaves	Lantadene A, a triterpenoid	Extreme muscular weakness, gastrointestinal irritation, lethargy, cyanosis, and hypotension; animals develop cholestatic jaundice
Larkspur	<i>Delphinium ajacis</i> and other species	Entire plant, seeds	Diterpene alkaloids, mainly delphinine	Ingestion in cattle produces gastroenteritis, weakness, respiratory depression, salivation, hypotension, and cardiac arrhythmias; human exposures are rarely reported
Lily of the valley	<i>Convallaria majalis</i>	Leaves, flowers, roots	The cardiac glycosides convallarin, and convallatoxin	Cardiac effects similar to other cardiac glycosides; dizziness and vomiting may occur within 1–2 hr after ingestion
Manchineel	<i>Hippomane mancinella</i>	Bark, fruit, leaves, and sap	Irritating ester with several triterpene compounds	Severe dermatitis with blistering can occur with contact of the sap or bark; conjunctivitis can result from eye contact; fruit ingestion leads to severe gastroenteritis, and in some cases laryngeal edema from local irritation

Mistletoe	<i>Phoradendron flavescens</i>	Entire plant, especially berries	$\beta$ -Phenylethylamine, tyramine, viscotoxin	Old literature cites several deaths among children attributed to eating the berries; tea brewed from berries has also been reported to cause fatality; acute gastroenteritis and cardiovascular collapse reported; no reports of toxicity in modern times other than gastrointestinal effects
Monkshood, aconite, wolfsbane	<i>Aconitum napellus</i> and other species	Roots, seeds, leaves	Aconitine	Alkaloids affect cardiac conduction; heart block or ventricular arrhythmias may occur; other effects include tingling and numbing sensation of the lips and tongue, blurred vision, gastroenteritis, and respiratory failure
Morning glory	<i>Ipomoea violacea</i> or <i>tricolor</i>	Seeds	Ergot alkaloids ergosine, ergosinine, and others; all chemically related to LSD	Powdered seeds are capable of inducing hallucinogenic effects after ingestion; may also cause nausea and vomiting
Mountain laurel, mountain ivy, laurel	<i>Kalmia latifolia</i> and <i>Kalmia angustifolia</i>	All parts	Andromedotoxin, a diterpene	Gastroenteritis, delirium, hypotension, weakness, lethargy, bradycardia
Narcissus, daffodil	<i>Narcissus</i> spp.	Bulb	Lycorine and other alkaloids	Severe gastroenteritis
Oleander	<i>Nerium oleander</i>	All parts	Cardiac glycosides, including oleandroside, oleandrin, nerioside	Severe gastroenteritis followed by cardiac arrhythmias, including heart block, ventricular tachycardia, and fibrillation; seizures can also occur
Yellow oleander	<i>Thevetia peruviana</i>	All parts		
Red squill	<i>Urginea maritima</i>	Bulb	Irritant in sap	Irritation to lips, tongue, and mouth; sap may blister skin and irritate eyes
Pencil tree, milkbush, spurge	<i>Euphorbia tirucalli</i> and other species	Leaves, stems, milky sap		
Philodendron	<i>Philodendron</i> spp.	Entire plant	Calcium oxalate or raphide crystals	Local irritation to mucous membranes, salivation, swelling of lips, and tongue may lead to difficulty in swallowing or respiration; no systemic effects have been reported
Caladium	<i>Caladium bicolor</i>			
Elephant ear	<i>Colocasia antiquorum</i>	All parts, even the smoke from burning plant	An oil resin called urushiol, which is made up of phenolic substances like 3- <i>n</i> -pentadecylcatechol	Produces a severe allergic response causing dermatitis upon contact resulting in inflammation, blistering, and vesicles
Poison ivy, poison oak, poison sumac	<i>Toxicodendron radicans</i> or <i>Rhus toxicodendron</i> and other species	Roots, leaves, or berries	Phytolaccine, pokeweed mitogen	Burning in mouth followed by severe gastroenteritis; may increase plasma cells in blood
Pokeweed, pigeonberry, inkberry, poke	<i>Phytolacca americana</i> , <i>Phytolacca decandra</i>			
Rhododendron, azalea	<i>Rhododendron</i> spp.	All parts	Andromedotoxin	Salivation, rhinorrhea, nausea, vomiting, diarrhea, weakness, labored breathing, coma (based on animal studies), hypotension
Rhubarb	<i>Rheum rhabarbarum</i>	Leaf blade (not the petiole, which is edible)	Oxalic acid	Abdominal pain, vomiting, diarrhea, headache, weakness; muscular cramps and tetany due to hypocalcemia may occur
Rosary pea, crab's eye, precatory bean, jequirity bean	<i>Abnus precatorius</i>	Seeds	The toxalbumin abrin	Seeds cause irritation of mouth and esophagus; symptoms resemble castor bean poisoning with severe nausea, vomiting, and diarrhea
Sweet pea	<i>Lathyrus odoratus</i>	Seeds	$\beta$ -Aminopropionitrile, $\beta$ -N-oxalyamino-L-alanine	Skeletal deformity and growth suppression in animals; lower extremity paralysis in humans
Texas mountain laurel, mescal bean	<i>Sophora secundiflora</i>	Entire plant	Cytisine, anagyrine	Salivation, gastroenteritis, headache, vertigo, confusion, dry mouth, hallucinations, coma, and convulsions; respiratory failure may occur

Continued

Table 10-1 Commonly Encountered Toxic Plants—Cont'd

Common Name	Scientific Name	Toxic Parts	Poisonous Principles	Symptoms
Threadleaf groundsel, groundsel	<i>Senecio longilobus</i> and other species	Entire plant	Pyrrolizidine alkaloids	Chronic ingestion may cause enlarged liver, cholestasis, ascites, abdominal pain, gastroenteritis
Tobacco (commercial)	<i>Nicotiana tabacum</i>	Entire plant	Nicotinic alkaloids	Nausea, vomiting, weakness, tremor, paralysis, convulsions, coma and death
Tree tobacco	<i>Nicotiana glauca</i>			
Wild tobacco	<i>Nicotiana trigonophylla</i>			
Indian tobacco	<i>Lobelia inflata</i>			
Wisteria	<i>Wisteria floribunda</i> , <i>Wisteria sinensis</i> , and other species	Entire plant including seeds and pods	Poisonous resin and a glycoside wistarin	Mild to severe gastroenteritis with abdominal pain
Yellow jessamine, Carolina jessamine	<i>Gelsemium sempervirens</i>	Whole plant, berries	Alkaloids, gelsemine and gelsemicine	Weakness, dizziness, blurred vision, bradycardia, respiratory insufficiency; seizures may rarely occur
Yew	<i>Taxus baccata</i> and other species	All parts, especially seed if chewed; fleshy red pulp of fruit least harmful	Taxine alkaloids	Severe gastroenteritis, abdominal pain, hypotension, respiratory insufficiency, myocardial depression; can cause dermatitis

**Box 10-1** Toxic Syndromes Produced by Plants

- I. Plants producing mucosal irritation due to edema, bullae formation, and salivation from the action of calcium oxalates and proteolytic enzymes during mastication
  - A. *Philodendron* spp.
  - B. Dumbcane (*Dieffenbachia* spp.)
  - C. Elephant ear (*Colocasia* spp.)
  - D. Jack-in-the-pulpit (*Arisaema triphyllum*)
- II. Plants producing gastroenteric irritation, including nausea, vomiting, diarrhea, and abdominal pain
  - A. Daffodil (*Narcissus pseudonarcissus*)
  - B. Autumn crocus (*Colchicum autumnale*)
  - C. Hyacinth (*Hyacinthus orientalis*)
  - D. Horse chestnut (*Aesculus hippocastanum*)
  - E. Pokeweed (*Phytolacca americana*)
  - F. Castor bean (*Ricinus communis*)
  - G. Rosary pea (*Abrus precatorius*)
  - H. Jerusalem cherry (*Solanum pseudocapsicum*)
- III. Plants with action on the cardiovascular system
  - A. Plants that contain cardiac glycosides and produce nausea, vomiting, and cardiac dysrhythmias
    1. Oleander (*Nerium oleander*)
    2. Lily of the valley (*Convallaria majalis*)
    3. Foxglove (*Digitalis purpurea*)
    4. Yellow oleander (*Thevetia peruviana*)
  - B. Plants that contain aconitine and produce nausea, vomiting, dysesthesias, hypotension, and bradycardia
    1. Monkshood (*Aconitum napellus*)
  - C. Plants that contain cyanotoxins and produce salivation, lacrimation, rhinorrhea, emesis, weakness, bradycardia, and hypotension
    1. Death camas (*Zigadenus* spp.)
    2. Azalea (*Rhododendron* spp.)
    3. Rhododendron (*Rhododendron* spp.)
    4. Mountain laurel (*Kalmia latifolia*)
- IV. Plants with nicotine-like activity producing nausea, vomiting, weakness, tremor, seizures, coma, and paralysis
  - A. Poison hemlock (*Conium maculatum*)
  - B. Wild tobacco (*Nicotiana glauca*)
  - C. Golden chain (*Laburnum anagyroides*)
- V. Plants containing atropine-like substances and causing antimuscarinic symptoms such as mydriasis, dry skin and mouth, urinary retention, tachycardia, and delirium
  - A. Belladonna, deadly nightshade (*Atropa belladonna*)
  - B. Angel's trumpet (*Solandra* spp.)
  - C. Jimsonweed (*Datura stramonium*)
- VI. Plants acting primarily on the central nervous system
  - A. Convulsants
    1. Water hemlock (*Cicuta maculata*)
  - B. Hallucinogens
    1. Peyote (*Lophophora williamsii*)
    2. Nutmeg and mace (*Myristica fragrans*)
    3. Morning glory (*Ipomoea* spp.)
- VII. Cyanogenic plants containing cyanogenic glucosides and producing acute or chronic cyanide poisoning
  1. Elderberry (*Sambucus canadensis*)
  2. Hydrangea (*Hydrangea macrophylla*)
  3. Tapioca plant (*Manihot esculenta*)
  4. Almond, apricot, cherry (*Prunus* spp.)
- VIII. Hepatotoxic plants
  1. Ackee (*Blighia sapida*)
  2. Comfrey (*Symphytum officinale*)
  3. Sassafras (*Sassafras albidum*)
- IX. Plant dermatitides
  - A. Contact urticaria—immediate hypersensitivity
    1. Stinging nettle (*Urtica dioica*)
    2. Cowitch (*Mucuna pruriens*)
    3. Bull nettle (*Cnidoscolus stimulosus*)
    4. Agave, century plant (*Agave americana*)
    5. Primrose (*Primula* spp.)
  - B. Irritant dermatitis
    1. Dumbcane (*Dieffenbachia maculata*)
    2. Philodendron (*Philodendron* spp.)
    3. Manchineel tree (*Hippomane mancinella*)
    4. Cow's horn (*Euphorbia grandicornis*)
  - C. Allergic contact dermatitis
    1. Poison ivy (*Toxicodendron radicans*)
    2. Poison oak—eastern (*Toxicodendron toxicarium*), western (*Toxicodendron diversilobum*)
    3. Poison sumac (*Toxicodendron vernix*)
    4. Ginkgo (*Ginkgo biloba*)
    5. Cashew (*Anacardium occidentale*)
    6. Mango (*Mangifera indica*)
  - D. Phytophotodermatitis
    1. Cow parsnip (*Heracleum lanatum*)
    2. Wild parsnip (*Pastinaca sativa* var. *pratensis*)
    3. Lime (*Citrus anrantiifolia*)

Adapted from Shih RD, Goldfrank LR: Plants. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al. (eds): Toxicologic Emergencies. Norwalk, Conn., Appleton & Lange, 1994, p 983.

**Treatment**

General management decisions regarding plant ingestion should be based on clinical findings on examination rather than purely on history of exposure (Box 10-2). Attention to airway, breathing, and circulation takes precedence over all other considerations. Gastric decontamination is rarely required for any type of plant ingestion because the patient is vomiting on arrival at the health care facility, presents with altered mental status or the possibility of becoming altered, or has ingested a nontoxic species. Activated charcoal will bind many toxic components of plants and can be administered in symptomatic cases or where toxicity is anticipated. Enhanced elimination of plant toxins with hemodialysis or hemoperfusion is rarely of benefit and should be reserved for the patient developing renal failure.

There are very few specific antidotes that can benefit victims of plant poisoning. The standard administration of oxygen, glucose, and naloxone should be considered in any person presenting with altered consciousness. Physostigmine can reverse some symptoms associated with antimuscarinic poisoning after ingestion of *Datura* and related species, but it can cause convulsions and heart blocks and should be used with caution. Cyanide-related toxicity seen with plants containing cyanogenic glycosides may be treated with nitrites and thiosulfate. Digoxin-specific Fab fragments may be of benefit to victims of cardiac glycoside poisoning. In most cases of suspected plant exposure and ingestion, patients will survive with supportive and expectant management of the airway and blood pressure.

**Box 10-2** General Management of Plant Poisonings

- I. Addressing life threats
  - A. Airway—active airway management including tracheal intubation is necessary in any patient with evidence of airway obstruction or inability to protect the airway.
  - B. Breathing—active airway management is also indicated in those patients with ineffective oxygenation or ventilation.
  - C. Circulation—may be compromised for several reasons:
    1. Gastroenteritis may cause significant fluid losses and necessitate aggressive intravenous rehydration.
    2. Some plant toxins cause dysrhythmias and direct cardiac toxicity.
- II. Identifying toxic syndrome
  - A. History and physical examination may reveal the likely cause of the exposure.
  - B. Examination of the plant in consultation with a toxicologist, poison center, or reference material.
  - C. Recognition of classic symptoms and signs associated with specific exposures:
    1. Antimuscarinic signs of dry mouth and skin, delirium, tachycardia, mydriasis, and hyperthermia can be seen in jimsonweed (*Datura stramonium*) and other anticholinergic species poisoning.
    2. Nausea, vomiting, and dysrhythmias will be seen in oleander (*Nerium oleander*) and other cardiac glycoside poisoning.
    3. Nausea, vomiting, and seizures will be seen in nicotine and water hemlock (*Cicuta maculata*) poisoning.
- III. Instituting therapy
  - A. Significant dermal and ocular exposures should be copiously irrigated.
  - B. Administration of oral-activated charcoal can decrease the absorption of most toxic plant materials.
  - C. Supportive care:
    1. Oral or intravenous rehydration for gastroenteritis.
    2. Maintenance of adequate mean arterial pressure through the use of vasopressors if necessary after appropriate fluid challenge.
  - D. Monitoring for cardiac dysrhythmias if the exposure warrants.
- IV. Antedotal therapy
  - A. The use of digoxin Fab antibody fragments may reverse cardiotoxicity from cardiac glycosides.
  - B. Physostigmine, when indicated to diagnose antimuscarinic poisoning.
  - C. Lilly cyanide antidote kit for cyanide poisoning resulting from cyanogenic plants or seeds.
  - D. Glucose for the treatment of ackee (*Blighia sapida*)-induced hypoglycemia.

**INDIVIDUAL TOXIC PLANTS****Ackee**

“Jamaican vomiting sickness” is caused by consumption of unripe ackee, the fruit of the tree *Blighia sapida*. Imported to Jamaica from West Africa in 1778,<sup>1</sup> the tree is also found in the Antilles, Central America, and is cultivated in southern

Florida. Ackee fruit is triangular in shape, 3 or 4 in. across, and straw to red in color. The fruit holds three shiny black seeds within fleshy edible material known as aril<sup>2</sup> (Fig. 10-1). Ripe ackee fruit splits open spontaneously to reveal the yellow aril. Fruit that has not split is unripe.<sup>3</sup> Canned ackee is available throughout the world, resulting in the first reported case of ackee poisoning in the United States.<sup>1</sup> Despite its potential toxicity, ackee fruit is an important part of the Jamaican diet.

**Toxin**

The major toxin responsible for Jamaican vomiting sickness was identified in 1955 and named hypoglycin A (L- $\alpha$ -aminomethylenecyclopropylpropionic acid). Isolated hypoglycin A causes severe hypoglycemia, vomiting, coma, and death in laboratory animals.<sup>4</sup> Ripe fruit contains less than 1.2 mg of hypoglycin A per 100 mg of aril. Unripe fruit, however, can yield up to 711 mg of hypoglycin A for every 100 mg of aril.<sup>3</sup> Hypoglycin A is metabolized by the liver to methylenecyclopropylacetic acid, an active toxic metabolite. This metabolite inhibits the transport of long-chain fatty acids into mitochondria, suppressing their oxidation. Inhibiting the utilization of these substrates of gluconeogenesis results in hypoglycemia after glycogen stores are consumed. Hypoglycin A also inhibits the dehydrogenation of several acyl-coenzyme As, causing an accumulation of serum fatty acids.<sup>5</sup> These acids may be responsible for some of the clinical manifestations seen in Jamaican vomiting sickness.

**FIGURE 10-1** Ackee (*Blighia sapida*).

### Presentation and Treatment

An estimated 5000 people have died in Jamaica since 1886 from ackee poisoning. Children ages 2 to 10 years are most often affected.<sup>5</sup> Symptoms begin with intense vomiting, followed by a quiescent phase that precedes more vomiting, seizures, coma, and death.<sup>6</sup> At the request of the Jamaican Ministry of Health, the U.S. Centers for Disease Control and Prevention investigated a series of patients with Jamaican vomiting sickness between 1989 and 1991. A total of 38 patients were identified. Vomiting was present in 77%, coma in 26%, and seizures in 24%. Eight patients (21%) died.<sup>7</sup> More than 75% of the cases occurred from January to March, and 28 (74%) of the patients were younger than 15 years old. Hypoglycemia with serum glucose levels as low as 3 mg/dL is a hallmark of the disease.<sup>6</sup>

Diagnosis requires recognizing the classic symptoms in association with recent ackee ingestion. Hypoglycemia and acidemia are the main laboratory abnormalities. Excess serum fatty acids can be detected using gas chromatography.<sup>1</sup> Treatment is supportive, focusing on rehydration, electrolyte replacement, and maintenance of normal blood glucose levels.

### Araceae

The Araceae family includes *Philodendron* and *Dieffenbachia* species. *Philodendrons* are indigenous to areas of Central and South America and can be found as ornamental indoor plants throughout the world<sup>8</sup> (Fig. 10-2). There are more than 275 species in the genus *Philodendron*. *Dieffenbachia* species are found throughout the tropical Americas and as houseplants. They have large ellipsoid leaves with characteristic pale-yellow central markings (Fig. 10-3).

### Toxin

*Philodendron* and *Dieffenbachia* have cells called idioblasts in their stems and leaves. These idioblasts contain needle-like crystals of calcium oxalate that can be released when a mechanical or chemical stimulus is applied. These cells are cigar-shaped and have a thick, rigid cell wall that forms a “nozzle” shape at either end. Each cell contains a bundle of 100 to 200 projectiles. When firing, the cell membrane covering the nozzle end ruptures and a single projectile is fired two to three cell lengths.<sup>9</sup> Animal experiments have shown that these calcium oxalate crystals alone do not produce a significant inflammatory response but are released with a proteolytic trypsin-like enzyme.<sup>10</sup> One theory suggests that the toxic substance accompanying the crystals is a bradykinin-like chemical, capable by itself of initiating an inflammatory response in the oral and pharyngeal mucosa.<sup>11,12</sup> Another hypothesis implies that the calcium oxalates or raphide crystals cause initial mechanical tissue damage, allowing the entry of proteolytic enzymes that cause inflammation.<sup>13</sup> The crystals can also penetrate the surface of the cornea and produce a keratoconjunctivitis.<sup>14</sup>

### Presentation and Treatment

Human toxicity results from mastication of the leaves or stems of the *Philodendron*, *Dieffenbachia*, and other members of the Araceae family. There is an immediate irritation of the

FIGURE 10-2 *Philodendron*.

FIGURE 10-3 *Dieffenbachia*.

mucous membranes, with a burning sensation, salivation, edema, and difficulty speaking. The difficulty in speaking gave *Dieffenbachia* its nickname “dumbcane.” A review of 188 exposures to *Dieffenbachia* and *Philodendron* from poison center data in the United States found only four mildly symptomatic cases. The authors concluded that *Dieffenbachia* and *Philodendron* exposures are rarely significant.<sup>15</sup> However, a published case reported severe airway compromise requiring emergency tracheostomy in an elderly man who bit into a *Dieffenbachia* stem thinking it was sugarcane.<sup>12</sup>

Treatment consists of local irrigation to remove the toxin. Observation for pharyngeal and oral swelling and control of the airway should be undertaken if necessary.

## Cassava

Cassava (*Manihot esculenta*) provides a major source of calories to approximately 300 million people throughout the tropics, including those in Nigeria, Zaire, Tanzania, Uganda, and Mozambique<sup>16</sup> (Fig. 10-4). The cassava tuber can be processed into several different foods known as garri, fufu, kpokpogari, and cassava flour. The chronic consumption of cassava has been linked to cassavism, the syndrome of tropical ataxic neuropathy (TAN).

## Toxin

Cassavism results from the toxin linamarin, a cyanogenic glucoside. Linamarin is hydrolyzed in the intestinal tract by

microbial flora releasing cyanide.<sup>17</sup> The cyanide is absorbed at sublethal levels and normally converted to thiocyanate.<sup>18</sup> Several environmental factors, including natural geographic variation in soil composition, influence the cyanogenic potential of cassava. Drought conditions raise the cyanogenic content. The most important factor influencing the development of toxicity seems to be the manner in which the fruit is prepared for consumption. Proper sun drying and thorough cooking of the fruit greatly reduce its toxic potential. Recent studies have also implicated toxins found in some cycads on West Pacific islands and in other tropical countries as causes of TAN.<sup>19</sup>

TAN may be caused by either chronic cyanide or thiocyanate intoxication. During a cassava-related epidemic of TAN in Mozambique that affected more than 1000 people, serum thiocyanate levels in those affected were 30 to 34  $\mu\text{mol/dL}$  (normal, 1 to 4  $\mu\text{mol/dL}$ ).<sup>16</sup> A dietary deficiency of sulfur-containing amino acids necessary for cyanide detoxification may also be a factor in the development of TAN.<sup>20</sup> The nutritional requirements of children and pregnant or lactating women make them more likely to show signs of toxicity.

Cyanide inhibits the enzyme cytochrome oxidase, preventing cellular respiration. Thiocyanate inhibits the enzyme fumarate hydratase in the Krebs citric acid cycle. Intact linamarin also inhibits the activity of Na-adenosine triphosphatase (ATPase). Animal studies of TAN have found hypokalemia, swelling, vacuolation of cells, and degeneration of myocardial fibers.<sup>18</sup> It is important to stress that cassavism is a clinical entity distinct from acute cyanide poisoning, and the exact mechanism of toxicity by this fruit is unknown.

## Presentation and Treatment

Tropical ataxic neuropathy (cassavism) is a syndrome characterized by bilateral primary optic atrophy, bilateral perceptive deafness, myelopathy, and peripheral neuropathy. The diagnosis requires two of these four features to be present.<sup>21</sup> The disease is also known by the local names *konzo* and *mantakassa*. The initial symptom is difficulty walking due to weakened lower extremity musculature. Symmetrical spastic paraparesis with increased muscle tone, hyperreflexia, and bilateral extensor plantar responses usually ensues.<sup>22</sup> Distal sensory loss is rare but the motor deficits are often permanent. One study in Mozambique demonstrated an incidence of ankle clonus in schoolchildren of up to 17%, correlating with high levels of cyanogens concentrations in cassava flour.<sup>23</sup> There is no effective treatment. Prevention of disease through proper food preparation is critical.

## Castor Bean and Rosary Pea

The castor bean plant and the rosary pea have similar toxins and are discussed together. *Ricinus communis*, the castor bean plant, is a shrublike herb that grows in the southern United States, Hawaii, and the West Indies. The plant can reach up to 15 ft high with large lobed leaves nearly 3 ft wide. The fruits are oval, covered with spines, and green or red in color. They contain three seeds 1/2 to 3/4 in. in diameter. The seeds are elliptic, smooth, glossy, and mottled with gray, black, brown, and white<sup>24</sup> (Fig. 10-5).

Seeds of *Abrus precator* are known commonly as the rosary pea, precatory bean, prayer bead, and crab's eyes. The rosary

FIGURE 10-4 Cassava (*Manihot esculenta*).

**FIGURE 10-5** Castor bean plant (*Ricinus communis*).

pea is found in Florida, the Caribbean, Hawaii, and Guam.<sup>25</sup> It is a vine with compound leaves and pale red-purple flowers containing toxic scarlet-red and black seeds (Fig. 10-6).

### Toxin

Castor beans contain the toxin ricin and the rosary pea contains abrin. Ricin and abrin are considered two of the most potent plant toxins. The estimated lethal dose of ricin in humans is 1.0 mg/kg.<sup>26</sup> They share a similar chemical structure: Each is a glycoprotein composed of peptide subunits named A and B that are linked by a disulfide bridge. The B chain binds to galactose-containing receptors on cell

surfaces and facilitates the entry of the A chain.<sup>27</sup> The A chain inactivates the 60S ribosomal subunit of eukaryotic cells and inhibits protein synthesis.<sup>28</sup> It is unclear how bioavailable these toxins are from the gastrointestinal tract.

### Presentation and Treatment

Castor beans and rosary peas must have their husks opened (usually by chewing) for severe toxicity to occur.<sup>29</sup> In a review of published castor bean ingestions since 1900, Challoner and McCarron<sup>29</sup> found 424 cases. Eleven deaths were documented. In only 3 cases was the fatal number of beans consumed quantified. Three adults died after eating

FIGURE 10-6 Rosary pea (*Abrus precatoris*).

three, five, and six beans. A total of 104 cases in the series were published with a description of clinical findings. Vomiting and diarrhea were the most common symptoms, each occurring more than 80% of the time. The acute gastroenteritis found in the most severe castor bean poisonings can cause dehydration, electrolyte abnormalities, vascular collapse, and death. The multisystem organ damage that can occur from parenteral administration of ricin and abrin has not been well documented in contemporary literature from oral ingestions of these beans, although one case report described self-limited hepatic transaminitis in a child following ingestion of castor beans.<sup>30</sup> Significant quantities of ricin can also be absorbed through inhalation, but this route of exposure is only clinically relevant in biological warfare.

Treatment begins with identifying the bean, determining if the husk was violated, and quantifying the exposure. Symptomatic patients may require admission to the hospital. Supportive care, including aggressive rehydration with intravenous fluids and electrolyte replacement, suffices in most cases. Challoner and McCarron recommend that patients who are asymptomatic but have chewed castor beans should be observed for 6 hours. If no symptoms are evident at that time, they may be discharged home with instructions to return if symptoms develop. Asymptomatic patients who likely did not chew the castor beans can be discharged after a shorter period of observation.<sup>29</sup> Diagnosis and treatment of rosary pea toxicity parallel that of the castor bean.

## Djenkol Bean

The djenkol tree (*Pithecellobium jiringa* or *Pithecolobium lobatum*) is found throughout Southeast Asia.<sup>31</sup> Djenkol beans are 3.0 to 3.5 cm in diameter and 1.5 to 2.0 cm thick and have a reddish-brown color. These beans are prepared by frying, boiling, or roasting and are also eaten raw. They are mainly consumed in Thailand, Malaysia, Burma, and Indonesia.<sup>32</sup>

## Toxin

Consumption of djenkol beans can cause acute renal failure (djenkolism). Predicting when consumption will cause disease is difficult for several reasons. Djenkolism can occur independent of the method of bean preparation. Cases have also occurred in only one member of a large family that consumed djenkol beans prepared in the same manner. Symptoms may arise in people who have eaten djenkol beans without prior problems, and beans may be safely eaten by former djenkol-poisoned patients without difficulty. Crystals are found in the urine of some patients and in animal models of poisoning, and they are composed of djenkolic acid ( $C_7H_{14}O_4N_2S_2$ ).<sup>31</sup> Despite the isolation of djenkolic acid crystals, the pathophysiology of djenkolism is unclear. Renal biopsies in some patients with djenkolism demonstrate acute tubular necrosis, whereas features of interstitial nephritis are infrequently described. Crystals are not consistently found in the urine of patients with djenkolism, however, arguing against an etiology of mechanical obstruction.<sup>33</sup>

## Presentation and Treatment

Males are afflicted by djenkol bean poisoning at a ratio of 9:1 compared to females, and the peak incidence is between September and January when the tree bears fruit.<sup>34</sup> Symptoms include colicky pain in the groin and suprapubic region with vomiting, diarrhea, dysuria, hematuria, and oliguria or anuria.<sup>35</sup> Needle-shaped crystals may be found on urinalysis. Supportive treatment with aggressive rehydration results in resolution of most cases. Djenkolic acid crystals are more soluble in alkaline solutions, and alkalinization of the urine may be of benefit.<sup>32</sup> The prognosis is good in symptomatic cases of djenkolism, as most patients recover with no permanent renal impairment.

## Khat

Leaves of the khat bush (*Catha edulis*), found in East Africa and Arabia, are used as a stimulant.<sup>36</sup> Several million people in these areas are habitual khat users, leading to medical and socioeconomic problems. Emigration from Africa and the Middle East has created a market for khat in Europe and the United States.<sup>37,38</sup> *Catha edulis* is a tall evergreen shrub with many centrally located small flowers and podlings. Its leaves are narrow and have serrated borders (Fig. 10-7).

## Toxin

The substance responsible for khat intoxication is the alkaloid cathinone ( $\alpha$ -aminopropionphenone). Cathinone is very similar in structure and action to amphetamine.<sup>39</sup> Brenneisen and colleagues<sup>36</sup> administered isolated cathinone

FIGURE 10-7 Khat (*Catha edulis*).

to volunteers in a double-blind, placebo-controlled crossover study and found increases in blood pressure and heart rate and feelings of euphoria. Khat acts by stimulating the release of norepinephrine and dopamine from presynaptic nerve endings, causing indirect stimulation of the central and sympathetic nervous system.<sup>40</sup>

#### Presentation and Treatment

Chewing of khat leaves produces a syndrome similar to that of amphetamine intoxication. Khat causes elevated blood pressure, mydriasis, hyperthermia, anorexia, insomnia, increased arousal, and elevated mood. Cerebral hemorrhage, myocardial infarction, and pulmonary edema have been associated with the use of this herb.<sup>41</sup> Khat abuse may cause psychological dependence, aggressive behavior, paranoid ideation, and even psychosis.<sup>39</sup> Fresh leaves are more potent than dried leaves and are preferred by habitual users. Long-term use of khat, especially in conjunction with ethanol and tobacco, may predispose to oral malignancy.<sup>42</sup>

Treatment parallels that of other sympathomimetic poisonings. Benzodiazepines counteract anxiety and agitation.

Hyperthermia is an important marker of serious poisoning and may require paralysis, artificial ventilation, and aggressive cooling measures when present. Supportive care measures also include hydration and monitoring for rhabdomyolysis. Patients may require addiction counseling for long-term abstinence.

#### Lantana

*Lantana camara* is a flowering ornamental found in the tropical Americas, the West Indies, Southeast Asia, Australia, New Zealand, and South Africa.<sup>43</sup> It is a perennial shrub with square twigs and simple leaves with toothed margins. Small tubular flowers—white, yellow, purple, or pink in color—are found in flat-topped clusters<sup>24</sup> (Fig. 10-8).

FIGURE 10-8 Lantana (*Lantana camara*).

## Toxin

The toxin responsible for poisoning from lantana has been debated. Most authorities now believe the toxin is a pentacyclic triterpenoid chemical known as lantadene A (22- $\beta$ -angeloxy-3-oxoolean-12-en-28-oic acid) found in lantana leaves and fruit. When administered to animal models, lantadene A can induce cholestasis, hepatotoxicity, and photosensitization.<sup>44</sup> However, animal models exposed to purified lantadene A may not demonstrate the same clinical syndrome found in human lantana poisoning.<sup>45</sup> One theory suggests that a separate triterpenoid more recently isolated from these plants, termed lantadene C, may be responsible for some of the hepatotoxic activity.<sup>46</sup>

## Presentation and Treatment

Human poisoning from *L. camara* is usually the result of children eating the unripe, green fruit. Presenting symptoms include vomiting, diarrhea, weakness, and lethargy. Presenting signs include cyanosis, labored breathing, photophobia, ataxia, decreased deep tendon reflexes, and coma. A 2-year-old child who died after consuming the green fruit of lantana was found to have acute pulmonary edema and circulatory collapse.<sup>47</sup> Consumption of ripe fruit does not cause toxicity.

Treatment is supportive. Gastric lavage may be considered in patients with a history of a large exposure who present within 1 hour of ingestion. Activated charcoal should be administered to all with a history of significant exposure to this plant and those who are symptomatic. All patients should be monitored 4 to 6 hours for signs of toxicity. Liver toxicity may be delayed.

## Manchineel

The manchineel tree (*Hippomane mancinella*) is an evergreen found in the West Indies, Central America, the Bahamas, South America, and the west coast of Africa. It is found in coastal regions because of an ability to thrive in a saline environment. The tree grows to 20 to 40 ft in height, has a trunk 1 or 2 ft in diameter, and is covered by smooth gray bark.<sup>48</sup> Manchineel trees produce a round yellow-green fruit known as "guavas."

Manchineels have been described as the most toxic tree on the North American continent.<sup>49</sup> In the United States, it is allowed to grow only in the Florida Everglades and in the Virgin Islands National Park. The aboriginal Carib natives understood the toxic properties of the manchineel tree and used its sap as an arrow poison and as a medicine. The tree is toxic to humans whose skin or mucous membranes contact its irritant sap and those who ingest its fruit or leaves.

## Toxin

The leaves, twigs, and bark of the manchineel tree contain a highly irritating latex sap. Adolf and Hecker<sup>48</sup> analyzed manchineel latex to determine the chemical cause of its irritant properties. They found a highly irritating ester of 5 $\beta$ -hydroxy-resiniferonol-6 $\alpha$ ,7 $\alpha$ -oxide with 9-, 11-, and 14-carbon chain fatty acids. The authors also found several triterpenes that proved to be tumor promoting in animal models.

## Presentation and Treatment

Skin contact with manchineel sap produces irritation and blisters. Severe dermatitis has occurred even from water falling on those seeking shelter from rain under a manchineel tree. The sap can cause an equally irritating conjunctivitis. In a review of 20 cases of manchineel conjunctivitis, 13 patients showed large corneal epithelial defects that resolved in a mean of 3.75 days.<sup>50</sup> Only 1 patient had a permanent stromal scar 5 years after exposure.

Ingestion of fruit induces lacrimation, salivation, vomiting, diarrhea, and central nervous system depression leading to coma and death.<sup>51</sup> Most non-life-threatening symptoms, such as oral and pharyngeal irritation, seem to subside over several hours.<sup>51</sup> An alkaloid substance resembling physostigmine has been implicated.<sup>52</sup> Ingestion of fruit can also produce life-threatening laryngeal edema through irritant effects on mucosa.

Decontamination is fundamental to the treatment of dermal and ocular exposure. Irrigation with copious amounts of water will limit the exposure. Ocular contact can also be treated with cycloplegics to relieve pain and prophylactic antibiotics while the cornea reepithelializes.

## Neurolathyrism

Consumption of the vegetables khesari (*Lathyrus sativus*), found in India, China, Ethiopia, and Nepal, can cause a devastating disease known as neurolathyrism.<sup>53</sup> Khesari is a readily accessible food source in developing countries because it needs no irrigation, fertilizers, or pesticides, and its seeds are high in protein.<sup>54</sup> Consumption of bread or other products produced from this crop can result in toxicity.

## Toxin

A neurotoxic amino acid,  $\beta$ -N-oxalylamino-L-alanine (BOAA), has been implicated in animal studies as the possible toxin responsible for neurolathyrism. In a primate model, oral consumption of BOAA alone caused a syndrome similar to neurolathyrism. BOAA in vitro inhibits the high-affinity uptake of glutamate transport by isolated synaptosomes, and it may inhibit mitochondrial complex I of the motor cortex and lumbar spinal cord.<sup>55</sup> Intrathecal administration of BOAA to rats demonstrated interference with the transport of aspartic and glutamic acid in spinal nerves.<sup>56</sup> The neuropathologic changes include loss of fibers in the pyramidal tracts of the spinal cord and pallor of the fasciculi gracilis.<sup>16</sup>

## Presentation and Treatment

Males are more likely than females to be affected after consuming khesari,<sup>57</sup> and the incidence is highest in the third and fourth decades of life. The syndrome appears after daily consumption of khesari for at least 2 or 3 months. Lathyrism usually occurs during famine conditions when the hearty crop becomes a majority of the diet. Initial symptoms are aching of the waist and rigidity of the calf muscles, known as *lodakas* in India. As symptoms progress, partial or total loss of control over the lower limbs occurs.<sup>53</sup> Some patients have exaggerated knee and ankle reflexes and ankle clonus. Sensory loss is

usually absent.<sup>16</sup> The neurologic changes are permanent but nonprogressive, and motor weakness of the upper extremities is rare. No specific therapy has been identified.

### Oleander

Naturally occurring cardiac glycosides are found in many plants. The two most common oleanders, *Nerium oleander* and *Thevetia peruviana*, are native to the Mediterranean region and most tropical and subtropical regions around the world, and they are found worldwide as ornamental plants. The flowers of *N. oleander* are white, pink, and dark red, and its fruit is a pair of long narrow pods (Fig. 10-9). *Thevetia peruviana* has yellow flowers and green fruit. Other plants containing cardiac glycosides are shown in Box 10-3.

### Toxin

Oleander contains the cardiac glycosides oleandrin, neriine, oleandroside, nerioside, and digitoxigenin.<sup>58,59</sup> Toxicity from oleander has been reported with the consumption of leaves and from the use of oleander twigs as skewers to cook meat.<sup>60</sup> The toxicity of oleander poisoning is indistinguishable from

FIGURE 10-9 Oleander (*Nerium oleander*).

### Box 10-3 Plants That Contain Cardiac Glycosides

- I. Figwort family (Scrophulariaceae)
  - A. Foxglove (*Digitalis purpurea*)
- II. Lily family (Liliaceae)
  - A. Sea onion (*Urginea maritima*)
  - B. Lily of the valley (*Convallaria majalis*)
- III. Dogbane family (Apocynaceae)
  - A. Yellow oleander (*Thevetia peruviana*)
  - B. Oleander (*Nerium oleander*)
  - C. Wintersweet (*Carissa spectabilis*)
  - D. Bushman's poison (*Carissa acokanthera*)
  - E. Sea mango (*Cerbera manghas*)
  - F. Frangipani (*Plumeria rubra*)
- IV. Milkweed family (Asclepiadaceae)
  - A. Balloon cotton (*Asclepias fruticosa*)
  - B. Redheaded cottonbush (*Asclepias curassavica*)
  - C. King's crown (*Calotropis procera*)
  - D. Rubber vine (*Cryptostegia grandiflora*)

acute digoxin toxicity. Cardiac glycosides inhibit the Na-ATPase pump in cardiac cells. Cardiac intracellular sodium and calcium rise; intracellular potassium falls. The slope of phase 4 in the action potential is increased, resulting in increased automaticity of cardiac cells. Cardiac glycosides also enhance vagal tone and prolong phase 3 of the cardiac action potential in the atrioventricular node and the His-Purkinje conduction system.<sup>61</sup>

### Presentation and Treatment

Accidental poisoning has occurred from chewing oleander flowers or leaves, eating meat cooked over burning oleander branches, and consuming liquids stirred with oleander stems. The ingestion of one oleander leaf is reported to be fatal.<sup>59</sup> The clinical presentation is very similar to acute digoxin poisoning, with nausea and vomiting the initial symptoms. Cardiac toxicity is manifested by many different dysrhythmias. Bradydysrhythmias, including sinus arrest, sinus bradycardia, and atrioventricular nodal blockade, may be seen. Tachydysrhythmias can include atrial tachycardia with block, junctional tachycardia, ventricular tachycardia, and fibrillation. Laboratory abnormalities include profound hyperkalemia.

Treatment of acute oleander ingestion includes gastric decontamination, correction of hyperkalemia, and standard treatment of cardiac dysrhythmias. The advent of specific antibody fragments against digoxin poisoning has revolutionized the care of digoxin-poisoned patients refractory to supportive therapy. The antibody fragments (Fab fragments) bind to and inactivate digoxin, with the resulting complex filtered by the kidney. The use of Fab fragments for the treatment of oleander toxicity in humans is limited to anecdotal case reports;<sup>60</sup> however, a study using high doses of digoxin Fab fragments for the treatment of oleander poisoning in a canine model was successful in reversing both dysrhythmias and hyperkalemia and prevented mortality.<sup>62</sup> A series from Sri Lanka demonstrated efficacy using multiple doses of activated charcoal in the management of *T. peruviana* poisoning.<sup>63</sup>

## Poison Hemlock

Poison hemlock (*Conium maculatum*) is found in North and South America, Europe, and as an ornamental in Asia. It is also known by the common names poison fool's parsley, hemlock, spotted hemlock, and California or Nebraska fern.<sup>64</sup> Poison hemlock grows to a height of 3 to 9 ft (Fig. 10-10). Younger plants have light green leaves that resemble those of a fern and have been mistaken for parsley. The large stems of maturing plants have purple spots. The fleshy white taproot has been mistaken for parsnips. Poison hemlock grows in groups along roadsides, in ditches, and in other uncultivated areas.

### Toxin

The toxins in poison hemlock are the piperidine alkaloids coniine and  $\gamma$ -coniine. The action of coniine is similar to that of nicotine. Animal studies demonstrate that coniine activity on isolated ileum and duodenum is blocked with atropine pretreatment. This implies that coniine stimulates parasympathetic ganglia and explains the observed nicotinic effects following exposure to this plant, which include salivation, mydriasis, and tachycardia, followed by bradycardia. These alkaloids also act as nondepolarizing antagonists at the neuromuscular junction, similar in action to tubocurarine.<sup>65</sup> Rhabdomyolysis and acute tubular necrosis have also been reported with poison hemlock ingestion.<sup>66</sup>

FIGURE 10-10 Poison hemlock (*Conium maculatum*).

### Presentation and Treatment

Symptoms are directly referable to the dual toxicity of the hemlock alkaloids. Salivation, urination, and defecation often precede the loss of tone in skeletal muscle. Death most frequently occurs due to respiratory arrest. There is no antidote; supportive care, including ventilator support and gastric decontamination, should be undertaken when the diagnosis of poison hemlock ingestion is suspected.

### Pyrrolizidine Alkaloids

The syndrome of hepatic veno-occlusive disease is found throughout the world associated with consumption of local teas. The disorder has been described in the West Indies, Afghanistan, India, and Israel. The rise in popularity of alternative medicine and the use of herbal teas has led to cases in Europe and the United States.<sup>67,68</sup>

### Toxin

The agents responsible for herbal-based hepatic veno-occlusive disease are the pyrrolizidine alkaloids. They are found in Jamaican "bush teas," comfrey (*Symphytum officinale*), grain contaminated with pyrrolizidine-containing weeds,<sup>69</sup> and in many other herbs used to prepare medicinal teas or dietary supplements. Approximately 3% of the world's flowering plants contain toxic pyrrolizidine alkaloids.<sup>70</sup> The dose and duration of exposure required for toxicity are unclear, and no "safe" level of exposure has been established.<sup>71</sup> Pyrrolizidine alkaloids are readily absorbed from the gastrointestinal tract and metabolized by the liver. The alkaloids undergo transformation to inactive or active metabolites by several metabolic pathways; they can be deactivated by *N*-oxidation or by hydrolysis of their ester bonds, or they can be activated by liver microsomal P450 enzymes that convert the alkaloid into a pyrrolic ester. Pyrrolic esters are potent oxidizers that can cause acute hepatotoxicity and cellular necrosis.<sup>72</sup> Chronic hepatotoxicity is also seen with pyrrolizidine alkaloid ingestion, and pathologic findings in animal models of this disease include enlarged hepatocytes.

Veno-occlusive disease results from nonthrombotic occlusion of the small intrahepatic branches of the hepatic vein by loose connective tissue. Damage to the venous endothelium leads to a proliferative fibrotic response resulting in occlusion. Veno-occlusive disease is defined pathologically as a progressive and concentric nonthrombotic occlusion of the lumina of small intrahepatic veins (diameter less than 300  $\mu$ m) by loose connective tissue with necrosis of hepatocytes in centrilobular areas.<sup>71</sup> Since false-negative biopsy results can occur, veno-occlusive disease is primarily a clinical diagnosis.

### Presentation and Treatment

The natural history of veno-occlusive disease includes acute and chronic forms. Acute veno-occlusive disease is characterized by ascites, abdominal pain, hepatomegaly, nausea, and vomiting. A cohort of 20 children with suspected pyrrolizidine poisoning in South Africa were examined. The prothrombin time was prolonged in 89% of patients, aspartate aminotransferase was elevated in all patients, and alanine

aminotransferase was elevated in 84%. A spectrophotometric test was developed by the investigators that detected pyrrolizidine metabolites in the urine. Mortality in this series was 40%.<sup>73</sup> Chronic veno-occlusive disease presents as cirrhosis with stigmata of liver disease.

Management of hepatic veno-occlusive disease is supportive. Sodium should be restricted and plasma expanders used to maintain oncotic pressure and limit ascites. Spironolactone is recommended for diuresis. Prostaglandin inhibitors are to be avoided to maintain renal blood flow in the presence of decreased intravascular volume.

### Water Hemlock

Water hemlock (*Cicuta maculata*) is found throughout North America. Water hemlock belongs to the family Umbelliferae and is related to European water hemlock (*Cicuta virosa*) and English hemlock or water dropwort (*Oenanthe crocata*).<sup>74</sup> Water hemlock is a perennial herb that grows from 3 to 7 ft with clustered, short, and thickened tuberous roots and hairless, purple striped, or mottled stems.<sup>75</sup> They have small, white, heavily scented flowers. Water hemlock roots are chambered (Fig. 10-11). A cut stem reveals yellow oily sap that smells like raw parsnip.<sup>76</sup>

### Toxin

The poison isolated from water hemlock is called cicutoxin. Cicutoxin is found in all parts of the plant, with the root containing the highest concentration.<sup>77</sup> Cicutoxin is an unsaturated aliphatic alcohol that acts primarily as a neurotoxin. Virol A is a component of *C. virosa* that has been found to inhibit GABA receptors in an animal model.<sup>78</sup> Poisoning can occur from ingestion or dermal exposure.

### Presentation and Treatment

A lethal dose of water hemlock can be contained in one rootstalk (rhizome).<sup>79</sup> Children have died from using the hollow stems as whistles or peashooters.<sup>80</sup> Onset of symptoms can occur within 15 minutes of exposure and initially includes nausea, vomiting, and abdominal pain. Early vomiting may be protective if undigested plant is expelled, but vomiting should not be induced due to the risk of aspiration during convulsions. Severe poisonings result in diaphoresis, salivation, bronchorrhea, and respiratory insufficiency. Death usually follows the development of intractable seizures. Rhabdomyolysis, renal failure, and severe metabolic acidosis may also be seen.<sup>81</sup> An examination of cicuta poisonings reported from 1900 to 1975 revealed 30% mortality.<sup>82</sup>

FIGURE 10-11 Water hemlock (*Cicuta maculata*).

Treatment is supportive; there is no specific antidote. Mechanical ventilation should be used when necessary. Convulsions should be treated with large doses of benzodiazepines or barbiturates. Adequate urine flow should be maintained to reduce the incidence of renal failure in the setting of rhabdomyolysis.

## Plant Dermatitis

Plant dermatitis is one of the most common mechanisms by which plants cause human disease. The number of plants that cause dermatitis is legion, and they are found throughout the world. Dermal exposure to some plants can be life threatening.<sup>83</sup> There are four main mechanisms by which plants cause human dermatitis: immediate hypersensitivity, irritant or mechanical dermatitis, phytophotodermatitis, and delayed hypersensitivity.

Urticariogenic plants cause immediate contact dermatitis. Some plants have stinging hairs that introduce irritating plant toxins through mechanical breaks in the skin (e.g., stinging trees of Australia and stinging nettle). Others cause a hypersensitivity response through direct contact alone (e.g., strawberry, castor bean, and chrysanthemum). Contact with these plants causes hives, pruritus, and sometimes anaphylaxis and shock.<sup>84</sup> Treatment of simple urticaria involves use of cold compresses and antihistamines. Systemic reactions may require more intensive therapy.

Many plants cause an irritant contact dermatitis. Simple mechanical irritation through spines or prickly hairs is one method by which plants cause human disease. The thorns of a flowering plant or spines of a cactus can penetrate the skin and cause fungal (*Sporothrix*), bacterial (*Staphylococcus aureus*), and other disease.<sup>84</sup> Chemical irritants are produced by some plants and can cause dermatitis. The manchineel tree, *Dieffenbachia*, and *Philodendron* are examples of plants that exert their toxicity through chemical irritation. Acute clinical findings include erythema, edema, and papular and vesicular reactions. In severe cases, bullae, pustules, and ulcerations may occur. Treatment of mechanical and chemical irritants revolves around removal of the irritating stimulus. This may include manual removal of thorns or copious irrigation of the skin to remove chemical irritants.

Phytophotodermatitis occurs when the skin is exposed to both a plant toxin and ultraviolet radiation. Celery, citrus, Queen Anne's lace, and the common fig can cause a dermatitis characterized by a painful, vesicular, erythematous rash that lasts for 1 or 2 weeks. Healing skin may show hyperpigmentation. Phytophotodermatitis is differentiated from allergic contact dermatitis by its presence only in sun-exposed areas and the finding of hyperpigmentation during healing.<sup>84</sup>

Allergic contact dermatitis results from cell-mediated immunity and is often referred to as a delayed hypersensitivity reaction. Poison ivy, poison oak, mango, and cashew can cause allergic contact dermatitis. The reaction only occurs in those previously exposed and sensitized to the plant. Exposed areas will show erythema, vesiculation, weeping, and pruritus. The lesions heal over several weeks and usually leave no residual scarring or pigmentation. Treatment of phytophotodermatitis and allergic contact dermatitis is similar. In mild cases, antihistamines and topical corticosteroids may provide symptomatic relief. More severe cases warrant the use of oral corticosteroids.<sup>84</sup>

## SUMMARY

Tropical plants contain a variety of components that can be toxic to humans and animals. New species and toxins are constantly being discovered and described in all areas of the world. Their effects are still unknown in human exposures. Some varieties, such as water hemlock and ackee, can cause life-threatening toxicity when ingested. More commonly, gastroenteritis is the hallmark of most plant exposures but can lead to weakness and dehydration in severe cases. The more common and better understood toxicities existing among plant species found in tropical and subtropical environments have been presented in this chapter. Most victims of these poisonings survive if administered aggressive support with airway protection and fluid rehydration.

## ACKNOWLEDGMENT

We thank Cinnamon Larson for the illustrations used in this chapter.

## Immunology, Host Defense, Immunodeficiencies, and Vaccines

PETER F. WELLER  
ANNE NICHOLSON-WELLER

### INTRODUCTION

This chapter (1) introduces the basic concepts of the innate and adaptive immune systems and their components; (2) examines how immune responses are regulated and directed to antimicrobial immunity; (3) considers deficiencies of the immune system that predispose to infections; and (4) discusses vaccines and their development. Fuller discussions of these topics are available in major immunology texts<sup>1-3</sup> and in the literature cited in the text.

The field of immunology grew out of early studies of host responses to infectious diseases, and now it is propelled primarily by gene knockouts in inbred strains of mice. The mammalian immune system is complex in both the number of cell types that are involved and the intricate levels of regulation that occur to maintain immunologic homeostasis with the internal and external environments. The scope and physical size of the pathogens that the immune system faces are diverse, ranging from intracellular viruses to very large metazoan parasites (Fig. 11-1). A number of immunologic mechanisms have evolved to handle this broad array of pathogens, and these mechanisms are dependent on the flexible capacity of the human immune system to recognize different foreign antigens. Conceptually, it is convenient to consider the immune system in two parts: innate and adaptive immunity. The innate system is phylogenetically older and the only immune system of simple organisms such as *Drosophila melanogaster* and *Caenorhabditis elegans*. In more complex organisms the innate system is retained, and, beginning at the level of bony vertebrates, an additional adaptive immune system functions. Differences between the innate and adaptive immune systems are summarized in Table 11-1.

### INNATE IMMUNITY

Innate immune mechanisms are inherited, invariant, and highly conserved throughout the evolution of nonfungal eukaryotes. These mechanisms have two important attributes: They

are always active and they can discriminate what is foreign to the host by recognizing the molecular patterns associated with prokaryotic and fungal pathogens (Tables 11-2 and 11-3). Both the skin and other epithelial surfaces are barriers against pathogens. Further, the mucosal fluid layer found in the respiratory, gastrointestinal, and genitourinary tracts functions as a physical barrier to deter pathogen access to target cells, as well as to supply a medium for washing pathogens away with the motion of peristalsis in the gut or the activity of ciliated epithelium in the airways. Other physical barriers are the various body cavities that are separated from one another by epithelial layers. Importantly, there is nonpathogenic flora, "friendly flora," which normally colonizes surfaces of the host and makes it more difficult for pathogens to colonize. A notable complication of antibiotic therapy is the decimation of antibiotic-sensitive normal flora throughout the host, which gives potential pathogens an advantage. Studies of the normal gut flora have shown that while the host provides unique niches for specific nonpathogenic flora, these organisms have an active role in inducing appropriate differentiation of the host enterocytes, downregulating the inflammatory mediators normally associated with bacterial colonization, and stimulating antibody diversity.<sup>4-6</sup> Thus, normal bacterial flora in the gut exists in a state of mutualism with the host.

**FIGURE 11-1** The infectious agents to which the human immune system must respond are diverse and range in size from large nematode and cestode helminthic parasites to small viral particles.

**Table 11-1** *Complementary Attributes of the Innate and Adaptive Immune Systems*

Attribute	Innate Immunity	Adaptive Immunity
Location of genes	Germline	Germline with significant rearrangements/mutations occurring in peripheral lymphoid tissues during life
Time of onset	From conception	During life, but only after exposure to specific immunogen
Discrimination of foreignness	Good	Poor
Specificity	Low	High
Capacity to contain invading pathogens	Low	High

### Sensors for Pathogens

There are fluid phase molecules as well as cell receptors that can recognize pathogens and trigger an innate immune response. The sensors of innate immunity recognize the vital, conserved molecular patterns that evolved on bacteria and fungi. These molecular motifs, which are not shared by metazoans and higher animals, are called pathogen-associated molecular patterns (PAMPs).<sup>7</sup>

### Host Fluid Phase Sensors for PAMPs

Some fluid phase sensors for PAMPs may also be effectors such as the defensins in the mucosal fluids, which bind and kill bacteria. Defensins are a family of cationic proteins in the 3500-kD molecular weight range, which are released by neutrophils and epithelial cells and are abundant in airway and gut secretions.<sup>8</sup> Human cathelicidin, hCAP18, has a distribution similar to defensins. Within the primary granules of neutrophils, hCAP18 is inactive; but once secreted, it is cleaved, yielding two antimicrobial peptides. The antimicrobial activity of both defensins and cathelicidins relies on their capacity to aggregate in microbial cell membranes and disrupt the membrane potential.<sup>8</sup> Located predominantly in the lung, surfactant protein A (SPA) and surfactant protein D (SPD) bind phospholipids and mediate their clearance by phagocytic cells. SPA and SPD can augment the clearance of certain bacteria, and they may be involved in the clearance of apoptotic cells.<sup>9</sup>  $\alpha$  and  $\beta$  interferons are stimulated by viral infections and exert antiviral activity by activating NK (natural killer) cells and coordinating an adaptive immune response.<sup>10</sup> Finally, natural antibody, which is almost exclusively IgM, is found in the plasma and body cavity fluids. Since there is no plasma membrane receptor for IgM, the subsequent disposal of the foreign microbe depends entirely on activating the complement cascade, which generates the effectors of host defense. Unlike most antibodies, the specificity of natural antibodies is largely invariant and determined in the germline genes: It is not influenced by T-cell help. Thus, natural antibodies are always present in each host, regardless of the “antigenic experience” of the individual. They are synthesized by the CD5+ or B-1 lymphocytes.

The complement system has three pathways for recognizing PAMPs: (1) the lectin pathway, which uses mannan binding lectin and ficolins as sensors<sup>11</sup>; (2) the classical pathway, which may be activated by direct C1q binding, or indirectly when “natural” IgM antibodies function as a sensor for PAMPs by binding microbial polysaccharides, cardiolipins, and phosphorylcholine and subsequently recruit C1q; and (3) the alternative pathway, which is activated by nonsialylated

carbohydrate PAMPs (Fig. 11-2). Serine esterases associated with mannan binding lectin (MASP-1 and MASP-2), and C1q (C1r and C1s) activate C4 and C2 to generate the C3 cleaving enzyme C4b2a shared by both the lectin and classical pathways. C3 activation is significantly amplified compared with other steps in the activation sequence, in part because C3 is present in plasma in higher molar concentrations compared with other complement components. C5 binds to C3b adjacent to C4b2a and once cleaved the resultant C5b condenses with C6, C7, C8, and C9 to form the nonselective C5b-9 channel, while C5a is released in the fluid phase. Although the C5b-9 complex is often referred to as the “membrane attack complex,” this is a misnomer. While there is no question that excessive C5b-9 activity is associated with pathology, under normal circumstances C5b-9 has hormone-like activity in that it can stimulate a calcium flux and activate G-coupled protein(s) in host cells, which can lead to a spectrum of cellular responses (reviewed in reference).<sup>12</sup> In terms of host defense, human deficiencies of C5, C6, C7, or C8 and to a lesser extent C9 are associated only with a predisposition to neisserial infections, suggesting that a critical role for C5b-9 is limited to these essential organisms.<sup>13</sup>

Evidence exists that the classical and alternative pathways are slowly turning over C3, and the same is likely for the lectin pathway.<sup>14,15</sup> Both fluid phase and membrane bound inhibitors keep the pathways in check until a PAMP is recognized, then the scale is tipped toward activation, which under most conditions is kept localized and transient.<sup>16</sup> The alternative pathway is activated when C3b is deposited on nonsialylated surfaces, which favors the binding of factor B, the homolog of C2, over the regulator factor H,<sup>17</sup> and can also be recruited when either the lectin or classical pathways have generated bound C3b. After binding to C3b factor B, a proenzyme, is cleaved by factor D to form the C3 cleaving enzyme C3bBb. Adjacent C3b provides a docking site for C5, allowing C3bBb

**Table 11-2** *Innate Immunity*

Barriers	Soluble Mediators	Cellular Mediators
Epithelial surfaces	Natural antibodies	Phagocytes
Mucous layers	Complement	Natural killer
Flushing motions	Cytokines	(NK) cells
Normal microbial flora	Mannan-binding lectin	
	Surfactant proteins A and D	
	Defensins	

**Table 11-3** Innate Immunity: Pathways for the Detection of Foreign Particles

Type of Foreign Substance	Fluid Phase Detecting System	Recruits Complement	Cell/Receptor
Viral associated abnormal or deficient MHC class I expression on host cells	—	No	Killer inhibitor receptors (KIRs) of natural killer (NK) cells
LPS	—	No	Toll-like receptor (TLR) 4, CD14
Diacylated bacterial lipoproteins	—	No	TLRs 2, 6
Triacylated bacterial lipoproteins	—	No	TLRs 1, 2
dsRNA	—	No	TLR3
Flagellin	—	No	TLR5
Unmethylated CpG DNA	—	No	TLR9 (intracellular)
Polyglucan carbohydrates	—	No	Glucan receptors dectinol and complement receptor 3 (CR3, CD11b/CD18)
Polymannose carbohydrates	—	No	Mannose-binding receptor (CD206) of macrophages
Polymannose carbohydrates	Mannan-binding lectin (MBL)	Yes	CR1(CD35), CR2(CD21), CR3
Bacterial carbohydrates	Natural Ab (IgM made by CD5+ B cells)	Yes	CR1,CR2,CR3
Nonsialylated carbohydrates	Alternative complement pathway	Yes	CR1,CR2,CR3
Negatively charged surfaces, complexes of anions-cations	Direct C1q binding	Yes	CR1,CR2,CR3
Phospholipids	Surfactant protein A (SPA)	No	Controversial
Phospholipids	Surfactant protein D (SPD)	No	Scavenger receptor

to cleave C5. The remainder of the pathway is shared by all three of the activation pathways.

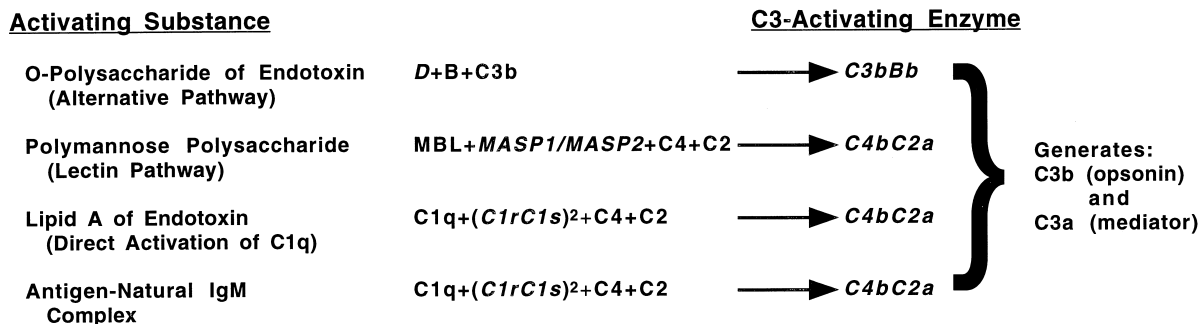

The complement proteins that potentially remain bound to the PAMP, mannan binding lectin, C1q, C4b, and C3b, are all opsonic and use the same receptor, namely complement receptor 1 or CD35,<sup>18–21</sup> which is expressed on erythrocytes and phagocytes, as well as some other tissues.<sup>22</sup> On erythrocytes, CR1 ligates complement opsonized particles and during passage through the liver and spleen, the particles are removed by resident phagocytes while the erythrocytes return to the circulation, a process known as immune adherence-mediated clearance. C3b, the major complement opsonin, in part because of its molar abundance, facilitates phagocytosis by neutrophils and monocytes. C3b can be further processed by the serine protease factor I to iC3b and then C3dg using as cofactors CR1 or H for the first step, and CR1 for the second step. Regulated processing of C3b generates C3 ligands that engage different receptors, each with distinctive cellular

expression. iC3b ligates CR3 (CD11b/CD18), which is expressed on neutrophils and macrophages predominantly; and C3dg ligates CR2 (CD21), which is expressed on B cells and dendritic cells predominantly.

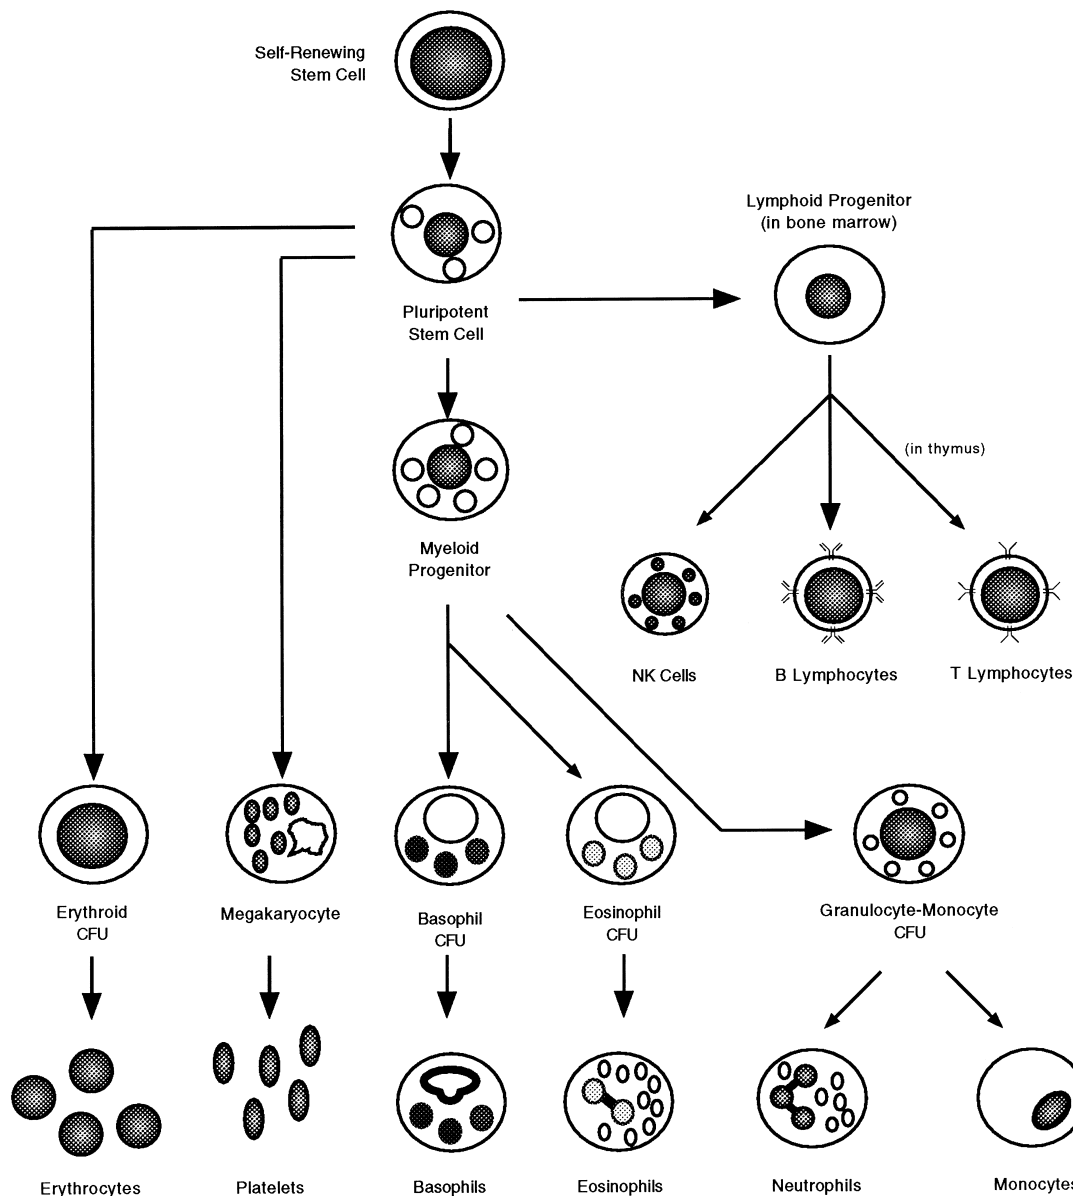

The fluid phase fragments of activation of C4, C3, and C5, namely C4a, C3a, and C5a, are known as anaphylatoxins. They reinforce the inflammatory response, but new appreciation of the widespread expression of receptors for C3a and C5a suggest that these anaphylatoxins are more broadly involved in biology. Indeed, C3a acting in the absence of C3aR potentiates the chemokine CXCL12 for the stimulation of bone marrow B cells, which demonstrates a role for complement in the maturation of the B cells.

### Cellular Components

Cellular components of innate immunity include phagocytic cells, NK cells, and the B-1 lymphocytes (those, as mentioned

**FIGURE 11-2** Complement pathways used in innate immunity. D and B, factors D and B of the alternative complement pathway; MBL, mannan-binding lectin; *MASP1/MASP2*, mannan-binding lectin-activated serine protease 1 and 2, respectively. Enzymes are shown in *italics*. The C5 cleaving enzyme for each of these pathways is the same as the C3 cleaving enzyme, except that it contains another C3b subcomponent that is necessary to bind the C5 substrate.

**FIGURE 11-3** Cells derived from a common progenitor cell include erythrocytes, platelets, and various types of leukocytes. The leukocytes are lymphocytes (natural killer or NK cells, B cells, and T cells), granulocytes (basophils, eosinophils, and neutrophils), and monocytes, which can further differentiate into macrophages. CFU, colony-forming unit.

previously, responsible for the production of natural antibodies). The phagocytic cells include the neutrophils and monocytes (Fig. 11-3), the latter of which, under the appropriate stimulus, can migrate into the tissues and become macrophages. One well-defined signal for phagocytes to migrate occurs when any of the complement detecting pathways is activated, leading to C5 cleavage and the generation of C5a, which is a potent chemotactic factor for neutrophils and monocytes. A myriad, 43 to date, of polypeptide chemoattractants, termed *chemokines*, also act as chemotactic factors with varying specificities for different classes of leukocytes depending on the expression of their cognate receptor(s).<sup>23</sup> Most often phagocytes depend on the complement system for recognizing the “foreignness” of the particle, and phagocytes

then have only to recognize the complement tag, usually C3b or iC3b, using CD35 and CD11a/CD18, respectively, as receptors. However, monocytes and macrophages can recognize polymannose and polyglucan directly by two receptors. The mannose receptor (CD206) (not to be confused with serum MBL) is a C-type lectin,<sup>24,25</sup> and there are two glucan receptors, Dectin-1 and the lectin-binding site of CD11a/CD18.<sup>26,27</sup>

The Toll-like receptors (TLRs) are widely expressed on host cells and are adapted for recognizing a spectrum of PAMPs (see Table 11-3). The intracellular TIR domain of TLRs shares homology with the IL-1 receptor and binds common adaptor proteins that lead to the activation of the transcription factors nuclear factor- $\kappa$ B (NF- $\kappa$ B) and/or interferon-related factor 3 (IRF3).<sup>28</sup> The activation of specific TLRs in different tissue

environments is now thought to direct a Th1 or a Th2 pathway of the immune response. The ability of different TLRs to recruit different adaptor proteins and the pairing of different TLRs provides for an appropriate immune response.

NK cells, which are directly cytotoxic to some transformed and bacteria- or virus-infected cells, have novel receptors for detecting these abnormal cells.<sup>29</sup> Some killer Ig-like receptors (KIRs) are stimulated by the normal distribution of MHC class I and have an intracellular immunoreceptor tyrosine-based inhibitory motif (ITIM) domain for inhibition. Thus, these KIRs would deliver a tonic inhibitory signal to the NK cell when it probed a normal cell. However, if the NK cell probed a cell with deficient class I expression, such as a virus-infected cell, KIR-mediated inhibition would be interrupted. Other KIRs, whose ligands are unknown, contain an intracellular immunoreceptor tyrosine-based activation motif (ITAM) activation domain. The CD94-NKG2 NK cell receptors are heterodimers with C-type lectin-like activity, and members of this receptor family may signal for either inhibition or activation of the NK cell. The ligands for these NK cell receptors are also host proteins that become induced during cell distress.

B-1 lymphocytes are derived from bone marrow stem cells, but unlike conventional B cells (also known as B-2 lymphocytes), B-1 cells are self-renewing. Mature B-1 lymphocytes do not undergo all the differentiation steps of conventional B cells, and thus have limited opportunity to rearrange and mutate their immunoglobulin genes. This is consistent with the fact that B-1 immunoresponsiveness has been selected over generations of a species to respond to common, invariant immunologic epitopes of pathogens.

## Synthesis

The innate immune system has a limited number of responses, all of which are encoded in the germline, meaning the genes originally inherited from the egg and the sperm. In contrast, the adaptive immune system has an almost unlimited array of responses because of ongoing genetic adaptation, which occurs in lymphocytes and is driven by the antigenic exposure of the individual. Why then does the more limited innate immune system persist in higher organisms? There are at least two reasons. First, the adaptive immune system requires time, on the order of days, to generate a useful antibody or cytotoxic T-cell response. In contrast, the innate immune response is operational immediately at the first encounter with a pathogen. Second, the adaptive immune response is not good at recognizing what is foreign, and so it requires the innate system to identify what is foreign and tag the foreign particle.<sup>30</sup> This recognition and tagging process primes adaptive immune responses.<sup>31</sup> On the other hand, the presence of specific antibody also enhances the function of the innate system, for example, antibody enhancement of NK cell function (antibody-dependent cell-mediated cytotoxicity) and the synergistic opsonic activity of specific antibody and complement. Thus, the innate and adaptive immune systems have evolved to function synergistically. Ironically, as vaccines are engineered to be more pure, the vaccine antigen(s) often escape detection by the innate immune system, and thereby become poor immunogens for the adaptive response (see Vaccines). Finally, we have outlined how the innate immune

system should work, but all successful pathogens have engineered strategies to avoid some key elements of the innate immune system. These strategies are discussed as the virulence factors in the chapters about specific pathogens.

## COMPONENTS OF THE ADAPTIVE IMMUNE SYSTEM

### Lymphoid Organs

The lymphoid system can be conceptually divided into a central and a peripheral system. The central system generates the lymphocytes from stem cells in the bone marrow and provides for further differentiation of B cells in the bone marrow and T cells in the thymus. The peripheral lymphoid system, on the other hand, is where the lymphocytes and accessory cells initiate adaptive immune responses. Peripheral lymphoid organs include tonsils, peripheral lymph nodes, spleen, and the mucosal lymphoid systems. In most lymph nodes, as well as in the spleen, lymphocytes are concentrated in the white pulp. T cells are found in the central region and B cells are found in the germinal centers, which are toward the periphery of the organ or node.<sup>1-3</sup>

### Cell Types of the Adaptive Immune Response

Many different cell types (see Fig. 11-3) participate in the various types of immune responses. Conventional B-cell development (B-2, not B-1) occurs totally within the bone marrow. As stem cells reproduce themselves, they also give rise to cells that will pass through the pro- and pre-B-cell lineages, eventually giving rise to mature B cells, which leave the bone marrow. The B cell receptor is comprised of membrane bound monomeric IgM, which conveys the antigenic specificity for the cell, and two associated invariant signalling molecules, Ig $\alpha$  and Ig $\beta$ . During B-cell maturation in the marrow, the heavy and light chain immunoglobulin genes are rearranged, allowing for a large repertoire of specificities. Most of the mature but naive B cells released from the marrow do not survive because they do not have access to the follicles of the peripheral lymphoid system. Activated B cells localize in the germinal centers of lymph nodes, and in that site further mutations of the immunoglobulin heavy and light chain genes occur, and selection leads to B cells capable of secreting high-affinity antibodies.<sup>1-3</sup> The immunoglobulin product of a B cell always has the same specificity as the Ig of the receptor. The properties of the five classes of human immunoglobulins are presented in Table 11-4.

T-cell precursors are generated in the bone marrow and migrate to the thymus where T-cell receptor (TCR) gene rearrangement takes place. The V, J, D, and C region genes come together to form the  $\alpha\beta$  and  $\gamma\delta$  TCRs. There is one specificity associated with each TCR, and after gene rearrangement to form the  $\alpha\beta$  TCR and  $\gamma\delta$  TCR, the TCR is expressed on the cell surface. TCR diversity is even greater than that for immunoglobulin owing to the large number of J and D region genes. Close to the time when TCR gene rearrangement occurs, the cells begin expressing several important accessory molecules (CD4, CD8, CD2, and CD3). During the process of T-cell maturation in the thymus, two other important maturation steps occur: positive and negative selection. During positive selection only

**Table 11-4** Physical, Chemical, and Biologic Properties of Human Immunoglobulins

Property	IgM	IgG	IgA	IgD	IgE
Molecular weight (kD)	970	160	170–340	184	188
Serum concentration (mg/dL)	45–150	800–1500	90–325	0–8	<0.025
Light chains	$\kappa$ or $\lambda$	$\kappa$ or $\lambda$	$\kappa$ or $\lambda$	$\kappa$ or $\lambda$	$\kappa$ or $\lambda$
Heavy chains (subgroups)	$\mu$	$\gamma 1, \gamma 2, \gamma 3$ , or $\gamma 4$	$\alpha 1$ or $\alpha 2$	$\delta$	$\epsilon$
J chain	Yes	No	In dimeric form	No	No
Time of synthesis*	First	Later			
Half-life in serum (days)	5	23	6	3	2.5
Localization	Serum	Serum, amniotic fluid, tissues	Serum, secretions, tears, colostrum, saliva, gastrointestinal and genitourinary tracts	Serum	Serum, tissues
Complement activation					
Classical pathway	++++	++	0	0	0
Alternative pathway	+	+	+	+	+
Opsonic activity	++	++++	0		
Lytic activity <sup>†</sup>	++++	++	0		
Inhibition of bacterial adherence	+	+	+++		
Viral neutralization	++	++	++		
Reaginic activity	0	Only IgG4	0	0	++++

\*Because IgM antibody is produced early in infection and usually does not persist after months, IgM antibody can be a indicator of recent infection. Further, IgM antibody does not cross the placenta (in contrast to IgG), so IgM antibodies against a pathogen in a neonate are indicative of intrauterine or postnatal infection of the child and are independent of maternal antibodies.

<sup>†</sup>Only through activation of complement.

those T cells which react with self-MHC can mature. During negative selection most T cells that recognize “self-peptides” are eliminated.<sup>1–3</sup>

T and B lymphocytes are the only cells that recognize specific antigens. B cells not only produce antibody, they also function as antigen-presenting cells. In contrast to B cells, T cells are also major regulators of the immune response and are involved in cell-mediated immunity.<sup>1–3</sup> While lymphocytes are the cell populations most identified with immune responses, the functioning of these cells is dependent on other types of cells arriving in sufficient numbers at the site where foreign antigen is found.

### Leukocyte Trafficking to Sites of Pathogen Invasion

A critical step in the immune system's response to pathogens is to recruit cells to enter an area of pathogen invasion or inflammation. Specific cell populations within the bloodstream are recruited to sites of pathogen invasion by interacting with molecules on the surface of the endothelium lining blood vessels or cavities. Innate immune sensors direct the release of IL-1 $\beta$  and TNF- $\alpha$  by cells at the site of pathogen invasion, which leads to the upregulation of E- and P-selectins on the surface of adjacent endothelial cells. Leukocytes, in contrast, express L-selectin constitutively. Initially, cells in the circulation are slowed down by weak binding orchestrated by the E- and P-selectins binding their counterreceptors, which are specific carbohydrates on the leukocytes.<sup>32</sup> While rolling adjacent to the site of inflammation, the cells receive a second signal through a chemokine or chemotactic receptor that activates the leukocyte's integrins for attachment to integrin ligands on endothelial cells. As a result of integrin ligation and signaling,<sup>33</sup> the leukocyte flattens and arrests on the endothelium, prior to migrating between or through endothelial cells

and across the extracellular matrix to the focus of infection. The process of leukocyte migration from the intravascular space to the extravascular space is known as diapedesis. A remarkable feature of diapedesis is that different integrin signals lead to the emigration of specific subpopulations of leukocytes.<sup>34</sup>

### MAJOR HISTOCOMPATIBILITY COMPLEX

The major histocompatibility complex (MHC), also designated HLA for “human leukocyte antigen,” is expressed on the surfaces of a large variety of cells and is translated from a region of highly polymorphic genes.<sup>1–3</sup> A number of very elegant studies in mice led to the MHC's being recognized as responsible for immune responses, and the region to which these genes mapped was called the Ir region for immune response genes.<sup>35</sup> These genes were subsequently shown to be necessary for activation of helper T lymphocytes, which are necessary for the production of T-dependent antibody. Later it was recognized that T cells do not recognize free or soluble antigens, but rather peptides of antigens that are bound to MHC. The MHC has two types of gene products: class I and class II. Class I consists of a transmembrane heavy chain, which is complexed to soluble  $\beta_2$ -microglobulin. All cells, with the sole exception of erythrocytes, express class I. Class II is composed of an  $\alpha$  and  $\beta$  transmembrane chain and is predominantly expressed on antigen-presenting cells. Both classes of MHC contain a “groove” in which processed peptide binds.<sup>36</sup>

### MHC and Antigen Presentation

The manner in which MHC class I and II molecules are synthesized and assembled determines which types of pathogenic peptides can be bound by them (Fig. 11-4). Some of the

**FIGURE 11-4** The pathways for processing antigens for presentation with major histocompatibility complex (MHC) molecules. Intracellular antigens (*left*), such as those derived from viruses, are degraded in the proteasome (1); complexed with TAP (transporter associated with antigen processing) (2); exported from the Golgi as an MHC class I antigen peptide complex (3), which are then expressed on the outer plasma membrane (4). Extracellular antigens (*right*) are phagocytosed or endocytosed (1), and degraded in lysosomes (2). Class II MHC molecules are synthesized and leave the Golgi in vesicles (3) that fuse with late endosomes containing antigenic peptides allowing the peptides to complex with MHC class II proteins (4); and the peptide-MHC class II complexes move to the plasma membrane (5). Cross-presentation (*center*) occurs when exogenous antigens, usually in a complex with apoptotic debris, are internalized by phagocytosis or endocytosis (1); move through a lysosomal compartment (2) to the proteasome (3). Thereafter, the degraded peptides are bound to TAP (4) for movement into the endoplasmic reticulum (ER) and Golgi for complexing with MHC class I proteins for transport and expression at the plasma membrane (5).

proteins synthesized endogenously by the host cell's ribosomes, as is the case for viral proteins, are normally degraded in the constitutive proteasome, an organelle designed to break down denatured or nonessential proteins to peptides. In the case of an intracellular infection, "immunoproteasomes" are induced by IFN $\gamma$  and replace some of the constitutive proteasomes. The two types of proteasomes have distinctive proteolytic specificities and thereby enhance the repertoire of available peptides being presented to T cells.<sup>37</sup> Some of these peptides are transported into the endoplasmic reticulum (ER) by the TAPs (transporters of antigen presentation), where peptides usually of 8 to 9 amino acids in length are loaded into the groove of nascently synthesized class I molecules. Finally, the MHC class I-peptide complex is transported through the Golgi complex and exocytosed to the cell surface.<sup>38</sup> Nonspecific peptides (foreign, e.g., viral, peptides) complexed with the MHC will be recognized. The T cells that recognize foreign peptides complexed to class I MHC activate cytotoxic CD8<sup>+</sup> T cells, which specifically lyse the virus-infected cell (Fig. 11-5). Because, potentially, any nucleated cell could be infected with a virus, all cells in the body, except erythrocytes, express class I MHC and are thereby

scrutinized by T cells for evidence of a foreign peptide. Host peptides are also presented by class I MHC, but are generally not recognized, since self-recognizing T cells are eliminated in the thymus and never circulate. Those T cells reacting with host peptides with low affinity can be removed in the periphery.

A different pathway of antigen presentation is followed for molecules synthesized outside the cell, such as those from the extracellular pathogen *Streptococcus pneumoniae*. In this case, antigen-presenting cells, which are primarily monocytes, macrophages, dendritic cells, and B lymphocytes, sample the extracellular milieu. This sampling might take the form of phagocytosis of particles, such as bacteria, by monocytes or macrophages, or endocytosis and pinocytosis of soluble samples by any of the antigen-presenting cells. The larger antigens are proteolytically degraded, and eventually the derived peptides end up in an endocytic vesicle, which contains class II MHC. The class II MHC was previously synthesized in the ER and then packaged in an endosomal compartment by the Golgi complex of the antigen-presenting cell. In an elegant process, antigenic peptides bind to the class II MHC and then are expressed on the surface of the antigen-presenting cell.<sup>39</sup>

**FIGURE 11-5** Responses of T-lymphocyte subsets to infectious agents. CD8+ T cells respond to antigens from intracellular pathogens, such as viruses, presented with class I major histocompatibility complex (MHC) molecules. These cytolytic CD8+ T cells lyse infected target cells by release of toxic proteins (perforin, granzyme) and by induction of apoptosis (programmed cell death) by engagement of Fas. CD4+ T cells can be directed to develop into T helper 1 (Th1) cells that stimulate macrophage killing of intracellular pathogens (cell-mediated immunity) or T helper 2 (Th2) cells that produce antibody or enhance eosinophil- and mast cell-mediated responses to helminthic parasites. GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN- $\gamma$ , interferon- $\gamma$ ; IL-4, etc., interleukins; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ .

It is the CD4+ helper T cells that recognize antigens bound to class II MHC. Again, as in the case of peptides expressed with class I MHC, the majority of peptides bound to class II MHC will be host-derived, but there will no T cells to react with the host peptides because those T cells will have been previously eliminated in the thymus by negative selection.

Two addenda to the classic distinction of class I and class II pathways of antigen presentation are necessary. First, although class I and class II MHC are efficient at presenting peptide antigens, lipid and glycolipid antigens, such as those derived from *Mycobacterium* species, are presented by CD1 proteins. Distinguishing features of the CD1 proteins are that they have limited diversity and their cytoplasmic tails target them to distinct endosomal compartments for the potential loading of lipids from different intracellular pathogens.<sup>40</sup> The second addendum to the class I/class II paradigm is the concept of “cross presentation.” Cross presentation occurs when an antigen made outside the antigen-presenting cell is internalized by endocytosis or phagocytosis and instead of complexing with class II MHC, it is routed to a compartment containing class I MHC (see Fig. 11-4).<sup>41,42</sup> At least one pathway involves digestion in the proteasome and complexing of the peptide with class I in the ER in the usual manner. Antigenic material that is from apoptotic infected cells or complexed with heat shock proteins from stressed or necrotic cells is favored for cross presentation.<sup>43,44</sup>

### Reason for MHC Diversity

In humans, the MHC, or HLA, genes are located on chromosome 6. There are three major polymorphic genes for class I (A, B, and C).<sup>1-3</sup> Because these genes are codominant, a cell will commonly express six different MHC class I molecules (three from each parent). The class II polymorphic genes are DR, DP, and DQ, all composed of  $\alpha$  and  $\beta$  chains. Many individuals also have a gene for an extra DR  $\beta$  chain, either of which can combine with the DR  $\alpha$  chain. Thus, class II MHC heterozygous individuals can express eight different polymorphic alleles (four from each parent). The reason an individual needs so many possible MHC proteins is to be able to generate a diverse array of grooves in the MHC molecules, such that there would be a groove to fit at least some antigens from each potential pathogen. Although this strategy works most of the time, there are some MHC types that have been linked to susceptibility to certain pathogens (see Tables 8-2 and 8-3), or to an increased frequency of certain immunologic diseases. The reason the human species maintains such a large and diverse MHC repertoire likely relates to the capacity to respond to numerous and diverse pathogens. Although an evolving pathogen might find a susceptible MHC-“deficient” type in a few individuals, others in the population will have different and functional MHC types and therefore will not be susceptible to the altered pathogen.

## Costimulation

Activation of T cells is not accomplished solely by the TCR complex binding to antigen in the cleft of the MHC. If this were so, then self-reacting T cells that escape negative selection in the thymus could induce autoimmune responses. Control of T-cell activation is in part regulated by a number of accessory molecules that must be engaged in order for the T cell to respond. These regulatory molecules are called “costimulatory” molecules.<sup>45</sup> While the presence of CD28 on T cells is constitutive, its ligands on the antigen-presenting cell, CD80 and CD86 (previously known as B7.1 and B7.2), are induced when innate immunity recognizes the PAMPs.<sup>46</sup> Ligation of lymphocyte CD40 ligand (CD154) by CD40 on the antigen-presenting cell stimulates the production of cytokines and allows for activation of integrins, which provide stable adhesion between the two cells and thereby enhances the possibility of stimulating an immune response.<sup>47</sup>

Complement C3 fragment C3dg can effect another type of costimulation. Antigens can directly interact with a B cell's immunoglobulin receptor and trigger a proliferative response. If, however, the antigen is first recognized as foreign by the complement system and tagged with C3b, which is processed to C3dg, the threshold amount of antigen needed to evoke a B-cell response is lowered by a factor of 10,000.<sup>31</sup> One reason C3dg-tagged antigen is efficient is that the CD21/CD19 signaling complex is costimulated with the antigen receptor. CD21 is the receptor for C3dg, while CD19 gives positive signaling to B cells.

The ability of the innate immune system to appropriately recognize pathogens and upregulate costimulatory molecules on antigen-presenting cells provides an important control over the immune system: Interaction between a peripheral lymphocyte that binds a self-antigen on an antigen-presenting cell that lacks costimulatory molecules leads to functional paralysis of the lymphocyte, or tolerance (*vide infra*).<sup>48</sup>

## Anergy and Tolerance

Anergy is a state of global immunologic unresponsiveness, which can be remedied by removal or addition of one or more factors.<sup>1-3</sup> For instance, an abundance of IL-10 leads to downregulation of molecules on antigen-presenting cells such that they are unable to activate T cells to respond in the presence of specific antigen. Removal of IL-10 from the system leads to restoration of responsiveness.

Tolerance is different from a state of anergy and occurs when the immune system is unable to respond to specific antigens.<sup>1-3</sup> Therefore, all other immune responses would occur normally except for the response to the specific antigen to which the organism has been made tolerant. There are multiple steps in the immune response that are susceptible to tolerance, and these steps are used as a safeguard to prevent the immune system from reacting against itself, so-called autoimmunity. During development, most T cells in the periphery are tolerant to self-antigens because those cells avidly reacting with self-antigens are eliminated in the thymus during “negative selection.” Immature B cells that react with multivalent self-antigens are destroyed by programmed cell death, or apoptosis, a process referred to as “clonal deletion.” Immature B cells that react with soluble self-antigens are rendered inactive by

the downregulation of their surface IgM and their signaling potential. Finally, when CD4+ T cells bind an antigen-presenting cell expressing antigen-MHC but no costimulatory molecules, these T cells will be rendered tolerant. Tolerance can be induced experimentally in animals and has been shown to be partially dependent on the form and the route of administration of the antigen. High doses of antigen, orally administered antigen, or repetitive doses of low concentrations of antigen may all lead to tolerance. Successful vaccine strategies must avoid inducing tolerance.

## MATURATION OF IMMUNE RESPONSES AND ANTIMICROBIAL IMMUNITY

Immune responses, initiated as outlined earlier, are subject to regulation that for antimicrobial immunity selects elements of the immune system adapted to contain specific pathogens and also regulates immune responses to minimize damage to surrounding cells and tissues due to uncontrolled inflammatory reactions.<sup>1-3</sup>

### Cytotoxic CD8+ T Cells

The presentation of cytosolic antigens, notably those of viral pathogens, will utilize class I MHC proteins and elicit responses of CD8+ T cells (see Fig. 11-4). Cytotoxic T cells are recruited by two mechanisms: (1) cross presentation by dendritic cells of host cellular debris containing microbial antigens, which leads to IL-2-dependent recruitment; and (2) in the case of antigen presentation by a nondendritic APC, the simultaneous binding of a CD4 helper T cell and a naive antigen-specific CD8 to the APC (see Fig. 11-5). CD8+ T cells are capable of eliminating infected cells by several mechanisms, including the release of granule-derived cytotoxins (granzyme, perforin) and the Fas ligand engagement of target cell Fas to elicit apoptosis (programmed cell death). Cytotoxic T cells also release cytokines that contribute to host defense. For instance, these cells release IFN- $\gamma$ , which inhibits viral replication and activates macrophage for intracellular killing and antigen presentation.

### CD4+ T Cells and Class II Presentation

Presentation of peptide antigens via class II MHC proteins is capable of stimulating CD4+ T cells. These cells differentiate from a common Th0 progenitor into cells with distinct phenotypes referred to as Th1 or Th2 cells. These two subsets of T helper cells were first defined in murine systems and have been further refined based on studies of murine strains infected with protozoal parasites, such as *Leishmania*, and helminthic parasites, such as schistosomes.<sup>49,50</sup> The T helper cell subsets are defined by the cytokines they produce. Th1 cells are characterized by IL-2, IFN- $\gamma$ , and IL-12 production. In contrast, Th2 responses are associated with IL-4, IL-5, IL-10, and IL-13 production. The two T helper subsets and the dominant cytokines of each are cross-regulatory: IFN- $\gamma$  from Th1 cells inhibits development of Th2 cells, and IL-10 and transforming growth factor- $\beta$  (TGF- $\beta$ ) made by Th2 cells inhibit Th1 development. In humans, unlike mice, there is more variability in T helper cells, especially among the cytokines they produce.

The processes whereby T helper cells differentiate into Th1 or Th2 subsets are currently thought to be influenced by the type of immature dendritic cell and its environment when it first presents the microbial antigen.<sup>51</sup> Because the type of the immature dendritic cell defines its repertoire of PAMP receptors, a given microbial antigen may preferentially be presented by a phenotypically distinct dendritic cell. In addition, the tissue microenvironment, with its distinctive exposure to foreign antigens and array of innate immune cells, influences the ability of resident immature dendritic cells to polarize T helper cells. Surrounding macrophages and NK cells that are stimulated by foreign antigens provide signals that bias the immature dendritic cell toward Th1, whereas stimulated mast cells and eosinophils bias the immature dendritic cell toward Th2.

### Th1 Responses: Cell-Mediated Immunity and Delayed Type Hypersensitivity

For intracellular pathogens that live within vesicles or vacuoles, such as mycobacteria, neither antibody nor cytotoxic T cells have access to the pathogens. Rather, macrophages harboring these pathogens must be activated by antigen-specific Th1 lymphocytes to kill the pathogens, a process called cell-mediated immunity.<sup>52</sup> The antigen-committed Th1 cells first recognize their cognate microbial peptide complexed with MHC class II on the surface of an infected macrophage, and then this lymphocyte secretes macrophage-activating cytokines, including IFN- $\gamma$ , TNF- $\alpha$ , and granulocyte-monocyte colony-stimulating factor (GM-CSF). CD40 ligand on the Th1 lymphocyte engages CD40 on macrophages and also contributes to macrophage activation. The “classically” activated macrophage uses upregulated nitric oxide and oxygen radicals to aid in killing of pathogens in phagolysosomes.<sup>53</sup> A less productive form of Th1 immunity is known as delayed type hypersensitivity. Contact dermatitis, such as sensitivity to poison ivy, is a common form of delayed type hypersensitivity.

### Th2 Responses: Antibody Production and Immediate Hypersensitivity

Th2 responses are important for host defense against extracellular pathogens, and Th2 cells participate in this in two different ways. First, Th2 cells are critical in activating B cells to produce antibodies. Activated Th2 cells express the CD40 ligand that must interact with CD40 on the surface of the B cell, and produce specific cytokines, such as IL-4 and IL-6, which stimulate B cells and promote isotype switching, whereby immunoglobulin synthesis matures from IgM to include other classes of immunoglobulins (see Table 11-4). Antibodies can function to directly neutralize some pathogens and toxins, to opsonize pathogens facilitating their phagocytosis by cells such as macrophages and neutrophils, and to activate complement for enhanced opsonization or lysis of some bacteria. Antibody may also enhance NK cell functions by means of antibody-dependent cellular cytotoxicity. A second role of Th2 cells is to “alternatively” activate macrophages to produce Th2 cytokines instead of Th1 cytokines. The end result is that the macrophage becomes more efficient at presenting peptides from extracellular microbes. Epithelioid cells and granulomatous fibrosis are the histologic hallmarks of alternatively activated macrophages.<sup>53</sup>

Activation of the Th2 pathway can lead to immediate hypersensitivity, an IgE-dependent form of allergy. The reaction is initiated when IgE antibodies that are bound via their Fc region to the IgE receptors, principally on mast cells, bind their specific antigens (“allergens”). Crosslinking of the IgE receptors on these cells stimulates the activation and release of mediators from these cells. IL-4 from Th2 lymphocytes strongly promotes the synthesis of IgE; the Th2 cytokines IL-5 and GM-CSF stimulate eosinophil differentiation and activation; and IL-4 acts on mast cells. IgE, eosinophils, and mast cells are involved in host defense against the extracellular helminthic parasites. On the other hand, a dysregulated Th2 response leads to chronic inflammation, asthma being a prime example.<sup>54</sup>

### Regulatory T Cells

Although it was speculated for some time that there might be a subset of regulatory T cells ( $T_R$ ), it was not until these cells could be identified by cell surface markers that definitive studies could be performed. In both mice and humans, the major population of  $T_R$  is CD25+, CD4+. CD25 is the  $\alpha$ -chain of the high affinity IL-2 receptor.  $T_R$  have rearranged T cell receptors and are antigen specific; many of them react with host antigens. Once activated, the  $T_R$  secretes IL-10 and TGF- $\beta$  and suppresses the immune response nonspecifically. The importance of  $T_R$  has been shown in mice and humans. Mice that are depleted of CD25+, CD4+ lymphocytes rapidly develop autoimmune disease; and in humans genetic deficiency of Foxp3 transcription factor, which is downstream of CD25 signaling, is associated with IPEX (immune dysregulation, polyendocrinopathy, enteropathy, and X-linked syndrome).<sup>55</sup> In normal subjects, lymphocytes reacting with self-antigens with high affinity are eliminated in the thymus.  $T_R$  are favored to bind lymphocytes that react with self- or nonself-antigens with low affinity, and thus are favored to remove self-reacting lymphocytes in the periphery.  $T_R$  proliferate in the periphery and are very radiosensitive. Loss of  $T_R$  may have a significant role in the development of autoimmune complications commonly seen after chemotherapy and/or radiation therapy.

## IMMUNOPATHOLOGY

### Autoimmunity

Tolerance to self is essential to maintain normal body functions. As discussed earlier (see Anergy and Tolerance), this is accomplished at multiple steps beginning early in development and continuing for the life of the organism. Autoimmune disease occurs when there is a breaking of tolerance to self-antigens. The autoimmune response may result from the incomplete elimination of autoreactive clones by the thymus. Alternatively, autoimmune responses may be elicited when normally hidden, sequestered self-antigens are released into the lymphoid environment and activate T cells. Lastly, autoimmune responses may be the result of the activation of formerly anergic T-cell self-reactive clones. Several genetic factors have been clearly associated with a risk of acquiring autoimmune disease. First, certain MHC alleles predispose to autoimmune disease, such as the association of the class I MHC B27 allele with ankylosing spondylitis. One possible explanation for why a specific MHC type is associated with a particular autoimmune syndrome is that the MHC protein is

more likely to bind a target host autoantigen. The converse, lack of peptide binding to MHC, is the explanation for the association of some host MHC types with susceptibility to specific pathogens (see Chapter 8, Table 8-1).

A second genetically determined risk factor for the development of autoimmune disease is the genetic deficiency of an early complement component. The relative risks for the deficiencies are C1q greater than C4 greater than C2.<sup>56</sup> A mild form of systemic lupus erythematosus (SLE) is associated with C2 deficiency, moderated SLE disease is associated with C4 deficiency, while a pernicious SLE-like syndrome is almost invariably associated with C1q deficiency.<sup>57</sup> There are at least two potential reasons why the absence of an early complement component predisposes to autoimmunity: (1) it is more difficult to clear potential autoantigens; and (2) it is more difficult to clear antigen-antibody immune complexes once they are formed.<sup>58</sup> Additional risk factors for autoimmune disease include the genetically determined upregulation of costimulatory molecules and a functional deficiency of T<sub>R</sub>.

### Other Forms of Immunopathology

Immune responses to infections may contribute to pathologic changes in other ways. When neither antibody nor antigen is singularly present in excess of the other, the complexing of antibodies with soluble antigen results in the formation of immune complexes that may cause disease. This may develop acutely as antibody titers rise, causing the syndrome of serum sickness. In addition, when soluble antigen is persistently abundant, there is sustained formation of immune complexes, leading to chronic immune complex-mediated tissue damage, as found in subacute bacterial endocarditis and chronic *Plasmodium malariae* infections.

The recruitment and activation of phagocytes in response to infections also may contribute to tissue damage owing to the exuberant local release of leukocyte granule enzymes and other proteins and generation of oxidants. Thus, the pyogenic response of neutrophils to bacterial infections can be partially deleterious, as with the chronic neurologic sequelae following bacterial meningitis in children. Likewise, eosinophil activation in response to helminthic infections and allergic diseases, such as asthma, can damage host cells.<sup>54</sup>

A serious condition known variously as hematophagocytic syndrome (HPS), hematophagocytic lymphohistiocytosis, and reactive macrophage activation syndrome is associated with macrophages in the bone marrow and spleen ingesting erythrocytes and sometimes nucleated blood cells.<sup>59</sup> The Th1 cytokines INF- $\gamma$  and TNF- $\alpha$  are largely responsible for the abnormally activated macrophages. A subgroup of those with a familial form of HPS have mutations in their perforin gene. More commonly, the condition is nonfamilial and associated with certain infections, including Epstein-Barr virus, herpes 6, malaria, and *Salmonella* infections; and HPS may also be associated with autoimmune conditions and leukemia.

### IMMUNODEFICIENCIES

Genetic deficiencies (see Chapter 8, Table 8-1), as well as acquired defects in the immune system may be associated with susceptibility to infections, and the pattern of infection—affected tissue and specific pathogen(s)—gives insight as to the defect (Table 11-5).<sup>60,61</sup> Many of the classic neonatal phenotypes of severe immunodeficiency states have now been recognized with a more moderate phenotype in adults. Thus, an appreciation of immunodeficient states is relevant for any age. The new onset of infection in a previously healthy host

**Table 11-5 Genetic Deficiencies Affecting Lymphocyte Functions**

Disease	Defective Gene Product	Resulting Defects
<b>T cells</b>		
Severe combined immunodeficiency (SCID)		
X-linked SCID	IL-2/IL-4 receptor $\gamma$ chain	T-cell proliferation, lymphopenia, antibody production, hypogammaglobulinemia
Non-X-linked SCID	JAK-3 kinase	T-cell proliferation, lymphopenia, antibody production, hypogammaglobulinemia
Adenosine deaminase deficiency	Adenosine deaminase	T-cell proliferation, lymphopenia, antibody production, hypogammaglobulinemia
Purine nucleoside phosphorylase deficiency	Purine nucleoside phosphorylase	T-cell function, decreased CD3+ cells
T-cell immunodeficiencies	IL-2, CD3 $\epsilon$ , CD3 $\gamma$ , or ZAP 70 tyrosine kinase	Infections, autoimmunity, allergies
HLA class II deficiency	C II TA; RFX 5	Impaired cell-mediated immunity
HLA class I deficiency	TAP2	Impaired cell-mediated immunity
DiGeorge syndrome		Thymic aplasia, cardiac abnormalities
Wiskott-Aldrich syndrome	WASP	Thrombocytopenia, low IgM, high IgA
Ataxia-telangiectasia	ATM	Low IgA, CD3 and CD4 cells
Immune dysfunction, polyendocrinopathy, enteropathy, and X-linked syndrome (IPEX)	FOXP3p	Severe autoimmunity
<b>B cells</b>		
X-linked hypogammaglobulinemia		Low antibodies
X-linked immunodeficiency with hyper IgM	CD 40 ligand	High IgM, low IgG and IgA
Common variable immunodeficiency		Low IgG and poor antibody response
IgA deficiency		Decreased IgA

**Table 11-6** Patterns of Infections Associated with Specific Immune Defects

Site/Organism	Typical Onset	Disease-Associated Defect
Recurrent meningitis <i>Neisseria meningitidis</i> <i>S. pneumoniae</i> , and other species	>12 years After trauma or surgery Anytime	Complement deficiency in properdin, C5, C6, C7, C8 or C9 Neutropenia, HIV
Severe aphthous ulcers Sinopulmonary infections <i>S. pneumoniae</i> , <i>S. pyogenes</i>	Neonatal	IgG deficiency, C3 deficiency, congenital neutropenia, dysfunctional PMN
<i>H. influenza</i> , <i>N. meningitidis</i> Pulmonary infections Atypical mycobacteria <i>Nocardia</i> spp.	Anytime Childhood–adult Adult	Common variable IgG deficiency Deficiencies of IFN $\gamma$ , IFN $\gamma$ R, IL-12 or IL-12R Alveolar proteinosis
Herpes virus I or II Severe EBV infection Bacteremia	Infancy Infancy–adult Anytime	NK cell deficiency X-linked lymphoproliferative disease HIV, hypo- or asplenia
<i>S. pneumoniae</i> , <i>S. pyogenes</i> , <i>H. influenza</i> , <i>N. meningitidis</i> <i>Salmonella</i> (nontyphoidal)	Anytime —	HIV, hemoglobinopathies, Bartonellosis, deficiencies of IFN $\gamma$ , IFN $\gamma$ R, IL-12 or IL-12R
<i>Neisseria gonorrhoeae</i> Skin infections <i>S. aureus</i>	Sexually active Childhood —	Complement deficiency in properdin, C5, C6, C7, C8, or C9 Leukocyte adhesion deficiency (deficiency or dysfunction of $\beta$ 2 integrins) Job's syndrome
Chronic granulomatous disease (genetic defects in neutrophil NADPH oxidase, impaired respiratory burst, and H <sub>2</sub> O <sub>2</sub> ) <i>Strongyloides stercoralis</i> <i>M. tuberculosis</i> relapse	Infancy–adult Anytime Anytime	<i>S. aureus</i> , <i>Salmonella</i> spp., <i>Burkholderia cepacia</i> , <i>Serratia marcescens</i> , <i>Nocardia asteroides</i> , <i>Aspergillus</i> spp., and <i>Chromobacterium violaceum</i> HTLV-1, glucocorticoid use, lymphoma HIV, glucocorticoid use

can herald the presence of an underlying acquired disease such as a hematologic malignancy and HIV infection, which are important to rule out first. The issue as to when it is relevant to consider a genetically determined immunodeficient state depends on the family history, age of the patient, and chronicity and pattern of infections; there are no easy rules. However, there are some recurrent themes such as the similar susceptibility of patients deficient in either IgG, neutrophils, or complement C3; and some “signature” organisms, such as the association of *Aspergillus* spp. and *Burkholderia cepacia* (Table 11-6).

## VACCINES

The capacity to elicit protective immunity against infectious agents was first achieved 200 years ago with the utilization of *vaccinia* (cowpox) by Jenner to protect against smallpox. The word *vaccination* derives from this first success. Immunization was critical in eradicating smallpox from the world and underlies the approach to the global eradication of other infections, including poliomyelitis. With the vaccines currently recommended by the World Health Organization (WHO) Expanded Programme on Immunization, significant mortality or morbidity from several infections can be prevented in children and adults. Among early childhood diseases, measles accounts for more deaths during childhood than any other vaccine-preventable disease. In 2002, WHO estimated that there were 30 to 40 million cases of measles with more than 700,000 deaths, mostly occurring in developing

countries. Thus, at present, delivering available vaccines to at-risk populations is as great a problem as the development of new vaccines. WHO maintains a web site giving the immunization status of any given country or region for the previous year: [www.who.int/vaccines-surveillance/DataDown.htm](http://www.who.int/vaccines-surveillance/DataDown.htm).

## Immune Responses

Early vaccines were based on the administration of either killed or live attenuated organisms in the hope that they would stimulate protective immune responses. Organisms treated with formalin are nonviable but still immunogenic. Attenuated human viruses are derived by passaging virus in culture on nonhuman cells during which the virus mutates and loses its pathogenicity but retains its immunogenicity for humans. Based on experience and the evolving understanding of immune responses, both the limitations of existing approaches and newer strategies to elicit the development of protective immunity are being appreciated. Rational approaches to vaccine development will take account of: (1) the need to engage the innate immune system so that co-stimulatory molecules on the antigen-presenting cell are upregulated, (2) the immunization site most likely to engage effective dendritic cells, and (3) the means to avoid T<sub>R</sub> cell blunting of the immune response. In addition, the immune condition of the subject must be considered. The efficacy of immunizing infants with live attenuated viral vaccines is compromised by maternally acquired antibody, so that immunizations with measles, mumps, and rubella must be delayed

until about one year of age. The immune system of children under age 2 is incapable of responding to immunization with bacterial polysaccharides, such as those needed for pneumococcal and *Haemophilus influenzae* type b (Hib) vaccinations. The conjugation of the bacterial polysaccharide with a carrier protein, as now employed in conjugate *H. influenzae* and *S. pneumoniae* vaccines, facilitates Th2 cell interactions. This occurs because the B cell specific for the microbial polysaccharide will internalize the carbohydrate-carrier complex via its B cell Ig receptor and process and then present in a MHC class II complex the carbohydrate as well as peptides from the carrier protein on its surface. This allows the B cell, which can only make Ig against the carbohydrate, to receive additional T-cell help from T cells that recognize the carrier protein peptides. With this additional T-cell help, a B cell is more efficiently stimulated to produce protective antibodies directed to the bacterial polysaccharides. This strategy circumvents the age limitation in the development of immune responses, enabling such conjugate vaccines to be administered effectively to infants, those most at risk of serious infections.

In addition to the chemical form of the immunogen, immune responses are governed by the site of immunization and by the presence of agents that can bolster immune responses. While intravenous administration of antigen can lead to tolerance of B and T cells, intradermal or subcutaneous administration facilitates uptake of antigen by antigen-presenting dendritic cells, thereby enhancing immune responses.<sup>62</sup> Administration of antigens at mucosal surfaces (e.g., intranasally or orally) may be less effective in terms of stimulating systemic immunity because dendritic cells in these areas are programmed to dampen immune responses. Nevertheless mucosal immunity can be important in preventing the spread of pathogens. Coadministration of an immunogen with adjuvants, substances that stimulate innate immunity, can enhance and influence the nature of the immune response. In diphtheria-pertussis-tetanus (DPT) immunizations, *Bordetella pertussis* functions as both an adjuvant and an immunogen. Aluminum hydroxide gel, alum, an adjuvant currently approved for use in humans, elicits a predominantly Th2-type T-cell response, leading to enhanced antibody formation. In contrast to some infections, Th1-type CD4+ T-cell responses with enhanced intracellular killing or cytotoxic CD8+ T-cell responses will be needed to ensure effective immune responses after immunization. Ongoing research is actively evaluating different strategies to develop newer adjuvants to enhance the efficacy of immunizations.

Cytokines are potential biologic agents that might have utility in directing specific types of immune responses. In experimental animal systems, the coadministration of the cytokine IL-12 with a vaccine can promote strong Th1 responses. Problems associated with cytokine use are toxicity and cost. Further, it is not known how administration of cytokines might influence responses to other organisms that person might harbor.

### Vaccine Formulations and Delivery

The ideal attributes for a vaccine are: (1) safe for all ages; (2) effective, long-lasting immunity; (3) requires only a single, or two closely spaced, immunizations; (4) provides protection within 2 weeks; (5) can be delivered without need of a needle and syringe; (6) may be administered in a formulation with

other vaccines; (7) is stable at high and low temperatures; and (8) is inexpensive to produce.<sup>63</sup>

The initial era of vaccine development was based on the use of killed or attenuated whole organisms as immunogens. Usually these produced reasonable immune responses because of their recruitment of innate immunity, but in some cases they are associated with adverse reactions. Examples of adverse reactions would include the encephalopathic responses to the older formulations of killed *Bordetella pertussis* vaccine and the allergy to contaminating egg protein of influenza vaccine, which is produced by growing the virus in chicken eggs. To avoid such issues, many newer vaccines use purified molecules as immunogens.

### Subunit Approach to Vaccines

Subunit vaccines are composed of purified recombinant proteins or synthetic peptides encoding defined epitopes of potential pathogens. Four reasons have led to the recent emphasis on using subunits of organisms as vaccines: (1) avoidance of the potential toxicities of whole organisms, such as those associated with killed pertussis vaccine; (2) provision of more stable vaccines, especially as compared with the care needed to keep live, attenuated strain vaccines active; (3) obviation of the high cost of growing fastidious organisms or organisms with complicated life cycles, such as malarial parasites; and (4) the feasibility of the subunit approach using molecular biologic recombinant technology.

Although there are benefits to recombinant subunit vaccines, one limitation is they are not very immunogenic when administered by themselves. Highly purified immunogens may not stimulate the innate immune system and fail to upregulate the costimulatory molecules on antigen-presenting cells, and thus fail to induce an immune response. The advantage of using whole organisms is that the innate immune system can recognize the organism as foreign, and thereby use complement and the upregulation of costimulatory molecules to induce an immune response.

One way to compensate for their lack of immunogenicity is to combine the purified subunits with more immunogenic adducts or administer them with newer adjuvants. A complex of the recombinant immunogen and recombinant complement C3dg is an appealing adduct because of its potential to recruit not only the B cell receptor, but also the CD21/CD19 complex, which potentiates the B cell response. Newer and more potent adjuvants include MF59, which is a lipid-detergent mixture containing squalene; F127, a copolymer that can be mixed with the immunogen and other immunomodulators at a cool temperature and, when injected, the mixture gels at body temperature providing a solid phase depot of immunoreactants; and the use of unmethylated CpG DNA, which is able to directly Toll-like receptor 9, which in humans is primarily expressed on B cells and plasmacytoid dendritic cells.<sup>64,65</sup> Although the development of new adjuvants is a burgeoning field, acceptance of this technology for human use has lagged because of concerns of inducing autoimmunity.<sup>66</sup>

### DNA Vaccines

A major innovation in vaccine delivery systems developed in the 1990s has been the transfection of mammalian cells with “naked DNA.” This method of vaccination simply

requires that the coding DNA for the candidate vaccine antigen be placed into a plasmid, usually containing a strong eukaryotic promoter such as cytomegalovirus. Purified plasmid in saline is then injected intradermally or intramuscularly and transfection of cells occurs. The transfected cells produce the candidate antigen, which, being intracellular, is processed and then expressed on the cell surface via class I MHC. If the cell is lysed, additional candidate antigen is released, which can then be processed via the extracellular class II pathway, or the cross-presentation pathway (see Fig. 11-4). Thus, via this methodology it is possible to generate MHC class I- and MHC class II-dependent responses to the candidate antigen.

Advantages of this method are that no adjuvants are required, the vaccine does not require special storage because DNA is stable, and the purification of plasmid DNA is relatively simple compared with purification of recombinant proteins. It is possible to enhance DNA vaccine efficacy by the coinjection of other plasmid DNA, which either contains the coding regions for molecules that will function as adjuvants or includes noncoding regions of DNA that themselves elicit adjuvant activity. Notably, the costimulatory molecules CD80 and CD86 have been incorporated into plasmid DNA, as well as the coding region for IL-12. Thus, one can attempt to direct the nature of the ensuing immune response via the local production of these molecules. For cytokines, this approach is particularly attractive, as the plasmid DNA stays local when injected intramuscularly.

There are potential drawbacks to the use of DNA vaccines. The most serious concern would be that the plasmid DNA becomes integrated into the genome, where any number of integration-related problems may later appear, such as the activation of oncogenes. Other concerns are that the long-term production of candidate vaccine antigen might induce tolerance to the antigen rather than a protective immune response. Additionally, there is the worry that the use of DNA vaccines may lead to autoimmune diseases, owing to lysis of the cells and release of cellular components including DNA.

## Vaccine Delivery Systems

Molecular biologic approaches also enable novel methods of introducing immunogens into hosts that are not dependent on adjuvants. One promising approach is to incorporate the DNA coding sequence for the relevant antigen into a microbial vector that can be made innocuous and suitable for administration to humans. Several vectors, including genetically altered, avirulent *Salmonella* bacteria, vaccinia virus, bacille Calmette-Guérin (BCG) mycobacteria, as well as edible plants are being studied. In addition, formulations of vaccines that allow transdermal or transmucosal immunization would greatly facilitate large scale, or emergency immunization programs.

## CONCLUSION

Vaccines already exist that protect against life-threatening infections (e.g., rabies, diphtheria), and that can eradicate major diseases (e.g., smallpox, and maybe polio), prevent diseases in susceptible populations by the immunization of surrogates (e.g., rubella immunization to prevent congenital rubella syndrome, tetanus immunization to prevent neonatal tetanus), limit morbidity (e.g., hepatitis A), and prevent late

sequelae of infections (e.g., prevention of hepatitis B-associated neoplasms). Further, new insights from a fuller understanding of immunology coupled with recombinant technology offer the possibility of making current vaccines more effective and developing new vaccines for important infectious diseases, such as HIV, TB, and malaria. Yet the fact that over 1 million children die each year of diseases for which we already have vaccines (vaccine-preventable disease) underscores the social and economic factors that limit access to this highly effective means of disease prevention.

# Tropical Infectious Diseases and Malignancy

CATHERINE DE MARTEL  
JULIE PARSONNET

## INTRODUCTION

Cancer is commonly considered a disease of the industrialized world. Many maintain that the modern lifestyle—with its cigarettes, poor diet, and exposure to environmental pollutants—is the pre-eminent cause of cancer, and that malignancy is a price paid for development. Epidemiologic data largely support this viewpoint. Annual age-standardized cancer mortality rates per 100,000 population regularly range above 100 for females and 150 for males in industrialized nations, extending as high as 400 for certain urban minority populations in the United States. Cancer incidence and mortality rates are typically far lower in developing countries.<sup>1,2</sup> For example, Sri Lanka reports mortality rates of 65.3 for males and 62.9 for females.<sup>3</sup> Without question, the proportion of all deaths due to cancer in industrialized nations far exceeds that in the developing tropical nations.

It is incorrect, however, to conclude that cancer is not an important concern in developing countries. One must keep in mind that cancer remains a disease of the elderly. In poorer tropical countries, where acute infectious diseases, maternal and infant mortality, and trauma afflict all to many children and young adults, crude cancer rates—unadjusted for the age structure of the population—appear disproportionately low. Among the elderly of developing countries, however, as in industrialized nations, cancer is a leading cause of death. In fact, developing countries already bear the brunt of the world's cancer. Of the estimated 10.06 million new cases of cancer worldwide in 2000, 5.38 million (53.46%) occurred in the developing world, and this is almost certainly an underestimate.<sup>3,4</sup> In most developing countries, cancer registries are incomplete or nonexistent.<sup>5</sup> Moreover, cancer diagnosis, when registered, is often based on incomplete information, as diagnostic capabilities are limited and postmortem examinations are rare. Thus, the number, types, and distribution of cancer cases are not known with any reasonable degree of certainty.<sup>4</sup>

Despite these limitations, certain trends are apparent. The demographic and epidemiologic transitions that accompany economic development have led to a gradually increasing median age and a growing proportion of older persons throughout

the world. At present, approximately 8% of the population of developing countries is over age 60; this figure is expected to rise to 20% by 2050.<sup>6</sup> This trend, together with growing tobacco use, urbanization, industrialization, and disposable income, foretell a rapid increase in chronic disease, including cancers, in all but the very poorest countries.<sup>7</sup> Indeed, cancer is already a major public health challenge in some developing areas. Reported age-standardized mortality rates for both sexes and all sites are considerably higher today in tropical South America than they are in North America.<sup>3</sup> Nevertheless, it should not be assumed that populations of developing countries are homogeneous. Bassett and colleagues<sup>8,9</sup> have pointed out the extreme differences in cancer patterns of European and African residents of Harare, Zimbabwe. In a study of bladder cancers in Durban, South Africa, 95% of the tumors in whites and 30% in Africans were transitional cell carcinoma, while 53% of the African patients, but only 2% of the whites, had squamous cell carcinoma. Ova of *Schistosoma haematobium* were seen in microscopic sections of the bladder tumors in 85% of the patients with squamous cell carcinoma, but in only 10% of the patients with transitional cell carcinoma.<sup>10</sup> Such studies can be extremely useful in unraveling the etiology and epidemiology of cancer among populations by pinpointing differences in risk factors.

As an increasing proportion of the world's cancer burden falls on the developing countries, the demand will grow for costly and sophisticated resources for diagnosis and treatment of malignancies. All developing countries combined, with 84% of the world's population, account for only 11% of global health spending.<sup>11</sup> Therefore the inevitable increase in cancer incidence in tropical countries in future decades will provide a powerful economic incentive to focus on prevention to any extent possible. The questions are: what should we prevent and how do we prevent it?

## INFECTION AS A PREVENTABLE CAUSE OF CANCER

Acute infectious diseases are universally recognized as the major cause of premature mortality in developing countries, particularly among infants and children. Ironically, it is now evident that, among adults, many cancers are also caused by infectious diseases. Such an idea is not new. Early in the last century, Johannes Andreas Grib Fibiger received the Nobel Prize for reporting (incorrectly, as it turned out) that a nematode could cause malignant tumors in the stomachs of rats. Before they were discredited, Fibiger's ideas inspired others to explore similar avenues of research.<sup>12</sup> Thus began a field of research in infection-related malignancy. In this regard, Fibiger's work remains important to this day. He initiated a field of research but also illustrated its pitfalls. Determining true causal associations can be difficult. Moreover, even distinguishing true cancers from infection-induced proliferative lesions can be challenging.

That infection might lead to malignancy is often greeted with surprise and skepticism by individuals in developed countries, and belies ignorance about cancers that afflict developing countries. A popular book about cancer published in 1995 claimed that, "Viral infection appears to play a role in only a tiny minority of cancer.... Granting even that viruses may play a heretofore undiscovered role in other cancer, it is probably fair to say that undue attention has been given to this particular collection of agents. The same could be said for

infectious agents more generally.”<sup>13</sup> Until recently, infectious agents that cause cancer were termed “rare and inconsequential.” This view, though widely held 10 years ago, is now known to be erroneous. Worldwide, infection remains among the most important causes of cancer. The International Agency of Research on Cancer (IARC) estimates conservatively that 15.6% of all malignancies, and 21% in developing countries, are attributable to infectious agents.<sup>14</sup> In some countries, the proportion is substantially higher. For example, in The Gambia in the late 1990s, 62.5% of malignancies in men affected either the liver (of which 84% were considered attributable to hepatitis B or C) or stomach (at least 55% estimated to result from *Helicobacter pylori* infection). In Gambian women, 57% of cancers affect the liver, stomach, or uterine cervix (95% attributable to human papillomavirus, HPV).<sup>5,15</sup> In terms of overall mortality age-adjusted numbers, cancers of the stomach for men and cervix uteri for women both rank second

worldwide, while liver cancer ranks third and sixth for men and women, respectively.<sup>3</sup> Thus, while cancer may be widely perceived as a consequence of industrial and environmental pollutants, in actuality, infection with certain cosmopolitan pathogens is second only to smoking as a cause of death from malignancy (Fig. 12-1). In addition, certain agents such as *Opisthorchis viverrini* and human T-cell leukemia virus type 1 (HTLV-1) are significant causes of certain cancers in restricted geographic areas. While the number of cases is not extensive, these viruses are of interest in elucidating mechanisms of oncogenesis.

The impact of pathogen-induced malignancy is particularly pronounced in countries in the transition from third world to first world economies. Adults in these populations who were infected with carcinogenic microbes such as hepatitis B virus (HBV) or *H. pylori* in childhood are experiencing a rapid increase in life expectancy. Since each year of chronic

**FIGURE 12-1** Estimates of the three leading causes of cancer death, by region. (Adapted from Ferlay J, Bray F, Pisani P, et al: GLOBOCAN 2000: Cancer Incidence, Mortality and Prevalence Worldwide, Version 1.0. IARC CancerBase No. 5. Lyon, IARC Press, 2001. Limited version available from: [www-dep.iarc.fr/globocan/globocan.htm](http://www-dep.iarc.fr/globocan/globocan.htm). Last updated on 03/02/2001.)

infection adds to the cumulative cancer risk, the number of cancer cases related to infection in early life would be expected to parallel the overall increase in longevity.

Yet, in many respects, the predominance of infection-related cancer can be looked upon as good news. Infectious diseases are often preventable or treatable; therefore, knowledge of specific infectious causes and the epidemiology of the pathogens involved provide a blueprint for control of those particular malignancies. The feasibility of control is demonstrated by the dramatic decline in infection-related malignancy in industrialized nations. Gastric and cervical cancers, for example, were among the leading causes of cancer death in the United States as recently as 1945, but are now far less prominent. The decline of cancer at these sites occurred without the benefit of vaccines or specific interventions. Rather, general improvements in socioeconomic status, sanitation, and hygiene appear to be responsible for the substantial reductions in infection-related malignancy, as they have for many other kinds of infectious diseases in industrialized nations.

While chronic infections are significant causes of cancer in developing countries, they are not the only important class of carcinogenic exposure. In developing countries, as throughout the world, the primacy of cigarette smoking

cannot be overstressed. Lung cancer alone accounts for 12.8% of all new malignancies diagnosed worldwide.<sup>3</sup> Where cigarettes remain too expensive for the average person, they currently play a small role in causing malignancy. In many countries, as socioeconomic conditions improve, the prevalence of cigarette smoking rises accordingly, auguring poorly for the future. Also important is the relative absence of fresh fruits and vegetables from the diets of poorer countries. Exposure to dietary carcinogens such as mycotoxins and nitrates also magnify the cancer risk. Thus, although cancers related to infection may be quite common in developing countries, attention must be paid to other factors that can also be addressed by public health interventions.

## INFECTIONS THAT CAUSE CANCER

Many infectious agents have been posited to cause cancer. The IARC biannually reviews epidemiologic and basic science information on putative cancer-causing agents. It then classifies these agents as definite, probable, possible, or unlikely causes of cancer. To date, they have carried out extensive evaluations of liver flukes, schistosomes, *H. pylori*, hepatitis viruses, human herpesvirus 8 (HHV-8), HPV, HTLV, human immunodeficiency virus (HIV), and Epstein-Barr virus (EBV; Table 12-1).

**Table 12-1** Infectious Agents Purported to Cause Malignancy

Organism	Tumor	IARC Classification*	Attributable Fraction†
<b>Viruses</b>			
Hepatitis B	Hepatocellular carcinoma	Group 1	60%
Hepatitis C	Hepatocellular carcinoma and MALT lymphoma	Group 1	24%
Papillomaviruses 16 and 18	Cervical, anogenital cancers	Group 1	90%–98% for all viruses
Papillomaviruses 31 and 33	Cervical, anogenital cancers	Group 2A	
Papillomaviruses 2 and other papillomaviruses	Cervical, anogenital cancers	Group 2B	
HTLV-1	Adult T-cell leukemia	Group 1	1%
Epstein-Barr virus	Burkitt's lymphoma	Group 1	81%
	Non-Hodgkin's lymphoma	Group 1	
	Hodgkin's disease	Group 1	49%
	Nasopharyngeal carcinoma	Group 1	
	Gastric adenocarcinoma	NS	
HHV-8	Kaposi's sarcoma	Group 2A	
HIV-1	ID related cancers	Group 1	
HIV-2	ID related cancers	Group 2A	
<b>Bacteria</b>			
<i>Helicobacter pylori</i>	Gastric adenocarcinoma	Group 1	55%
	Gastric lymphoma		75%

†From references 14 and 15.

Other infectious agents that have not yet been evaluated by the IARC, but are suspected of causing cancer, are also listed in Table 12-1. Because the great majority of these pathogens are reviewed elsewhere in this book, we will not discuss their life cycles, epidemiology, or clinical manifestations. Instead, we focus here on the general features and control of the principal infection-induced malignancies.

A simplified scheme of infection-related oncogenesis can be used to categorize the malignancies into one of two types: either tumors caused by the integration of oncogenic DNA into the host cell or those induced by chronic inflammation. Basically, all types of oncogenic agents enhance cell growth. The mechanisms by which this occurs can be quite variable, however, ranging from expression of viral oncogenes for cell growth factors to stimulation of growth by inflammatory intermediaries. Agents with oncogenes, however, directly immortalize cells, while inflammatory carcinogenic agents do not. Moreover, it is thought that immunosuppression may be important for development of malignancies related to oncogene integration. This is not thought to be the case for inflammation-related malignancy; in fact, immunosuppression, by lessening the inflammatory response, could potentially protect against inflammation-related cancers. This was highlighted in a recent review by Smukler and Ratner who state “the observed lack of a significant increase in the incidence of hepatocellular carcinoma [in HIV infected patients] may be caused, in part, by a possible reduction in HBV-induced hepatic damage in HIV coinfecting people. Immune impairment in HIV-positive patients leads to higher HBV replication levels with less severe liver damage because of a blunted HBV-specific immune response and less consequent cirrhosis.”<sup>16</sup> A disproportionate lack of necrotizing inflammation in HIV-HBV coinfecting subjects supports this possibility.<sup>17</sup> Finally, cancers related to inflammation appear to occur only after a long incubation period. There is no such temporal relationship between oncogenic viruses and cancer. This latter point is most readily demonstrated by the short incubation period between EBV infection and the development of Burkitt’s lymphoma in young children in sub-Saharan Africa.

The importance of inflammation in inducing cancer was first exemplified by two diseases not uncommon to the tropics: chronic, draining osteomyelitis and Buruli ulcers (caused by *Mycobacterium ulcerans*). These chronic, inflammatory conditions, if left untreated, cause aggressive squamous-cell carcinomas.<sup>18</sup> In each instance, carcinogenesis appears to depend not on specific oncogenic genes or gene products produced by the infectious agent, but rather on the organism’s ability to persist despite the host’s efforts to combat its presence. Inflammation is thought to induce cancer by stimulating production of reactive oxygen and nitrogen species that damage DNA, proteins, and membranes. Inflammation may also increase the proliferative rate of infected tissues, promoting development of tumors. Proliferation is a promutagenic effect, permitting more cells to be susceptible to DNA damage and mutation. It also fosters selective growth of mutant clones.<sup>19–23</sup> We now recognize that many infections, including *H. pylori*, *S. haematobium*, *O. viverrini*, and HBV, are at least in part linked to cancer by their ability to foster an inflammatory response. In support of this, phenotypes of *H. pylori* that cause more

inflammation are more closely related to malignancy.<sup>24</sup> Treatment of *S. haematobium* and *O. viverrini* leads to marked decreases in inflammatory cells within the bladder and liver, respectively, and associated declines in chromosomal damage.

As stated previously, the risk of developing inflammation-related cancer also appears to be intimately tied to the duration of the inflammatory process. This has been particularly well established for HBV infection but appears also to be the case for *H. pylori* and probably other agents as well.<sup>25,26</sup> The chronicity of infection implies that the carcinogenic effects of infection are likely to be promotional rather than resulting from a single initiating event.

Oncogenic viruses—such as EBV, HTLV-1, HHV-8, and human papillomaviruses—may lead more directly to cancer by integration of viral oncogenes or oncogene promoters into nuclear DNA. Resultant viral oncoproteins may for instance interact with and inactivate host tumor suppressor proteins such as p53, uncoupling normal growth control processes and leading to cellular transformation.<sup>27,28</sup> Oncogenic viruses may also induce production of cell growth factors, stimulating the host cell’s reproduction, and accordingly their own. Other viruses, such as HIV, are not direct carcinogens but, by limiting the host’s immune response, foster carcinogenic effects of normally more innocuous agents. For example, HIV-related cellular immunodeficiency fosters carcinogenesis by chronic colonizers such as EBV and permits infection with HHV-8, an unusual agent in immunocompetent hosts, with resultant Kaposi’s sarcoma (KS). KS in persons with HIV infection occurs at a rate thousands of times higher than in the non-HIV population.<sup>29</sup> In HIV-infected patients, lymphomas also occur at much higher rates than in the general population. Although the specific cause remains to be determined, much evidence points to the activity of lymphotropic viruses, particularly EBV. Whereas both EBV and HTLV-1 have long been implicated in the development of lymphoid malignancies, additional viral and bacterial agents are now thought to have lymphoproliferative activity. These include HHV-8, hepatitis C virus (HCV), *H. pylori*, *Borrelia burgdorferi*, and possibly *Campylobacter jejuni*.<sup>30–33</sup>

The etiology of infection-induced cancer is made more complex by multifactorial causality of certain tumors on the one hand, and multiple outcomes following certain infections on the other. The importance of a specific agent in causing malignancy (its “attributable risk”) depends on its prevalence. For example, in high-incidence areas of hepatitis, primary hepatocellular carcinoma (HCC) is commonly associated with chronic infection with HBV or HCV. Shin and associates<sup>34</sup> found strong evidence that HBV and HCV were independent risk factors for HCC in Korea, where liver cancer mortality is reported to be the highest in the world. In areas where hepatitis viruses are less prevalent, they will be a less common factor in HCC. In Sweden, for example, Kaczynski and coworkers tested 113 HCC patients for serologic or immunocytochemical evidence of such infection. They found no signs of chronic HBV infection, and HCV reactivity occurred in only 7 of 64 patients.<sup>35</sup> Thus, chronic viral hepatitis appeared to play a minor role in induction of HCC in Sweden, where alcohol-related cirrhosis is a much more common risk factor.

Certain infections may be important, but not sufficient, for the induction of cancer. Just as most smokers do not get lung cancer, most infections with potentially carcinogenic pathogens do not proceed to a malignancy. For example, the large and diverse group of HPVs is implicated in causation of a variety of proliferative conditions, some of which (warts, epithelial cysts, intraepithelial neoplasias, anogenital, orolaryngeal and oropharyngeal papillomas, keratoacanthomas, and other types of hyperkeratoses) are relatively benign. At least 90% of cancers of the cervix and more than 50% of other anogenital cancers are attributed to certain high-risk HPV types that may act as solitary carcinogens or in concert with cofactors. The progression of HPV-associated squamous epithelial lesions to cervical cancer may be enhanced by certain concurrent sexually transmitted agents, such as herpes simplex virus or chlamydia, and is clearly associated with HIV-induced immunosuppression.<sup>15</sup> Aflatoxin B1 is widely considered to be a cocarcinogen with HBV; although either is capable of inducing HCC, the combination appears to behave synergistically in regions where both agents are endemic.<sup>36</sup> Although 90% of the world's population is thought to be infected with EBV, the two tumors classically linked to EBV occur in limited geographic areas. Burkitt's lymphoma is found in hyperendemic malarial areas of Africa and New Guinea, and nasopharyngeal carcinoma in parts of Asia, suggesting the presence of specific, geographically limited, cofactors.<sup>37,38</sup>

## PREVENTION OF INFECTION-RELATED MALIGNANCIES

Each carcinogenic pathogen has unique features that may facilitate or frustrate efforts to control or prevent the associated cancers. Prevention at the primary level—that is, by blocking an initial infection—may be accomplished in the case of hepatitis B by immunization of infants with a recombinant DNA or plasma-derived vaccine. Such vaccine has already proved effective in protecting inoculated children against chronic carriage and hepatocellular carcinoma.<sup>38,40</sup> In Taiwan, an intensive vaccination program in newborns began in 1984. The incidence of hepatocellular carcinoma in children 6 to 9 years of age declined from 0.52 per 100,000 children for those born before the program to 0.13 for those born after, a reduction by a factor of four. Since 1991, HBV vaccine is recommended as part of the WHO's Expanded Programme on Immunizations (EPI). It is currently given as part of routine childhood immunizations in 141 countries with a global coverage rising from 15% in 1996 to around 45% in 2002. Unfortunately, it is the only vaccine currently available that is specifically targeted at an infection-induced malignancy in humans. Promising evaluation of a vaccine against HPV types 16 and 18, responsible for up to 70% of cervical cancers worldwide, has recently been reported, suggesting a need to consider vaccine delivery strategy targeting young women before the onset of sexual activity.<sup>41–43</sup> Other efforts are underway to develop vaccines against viral, bacterial, and parasitic agents, including EBV, HTLV-1, *H. pylori*, and *Schistosoma* species. Unfortunately, vaccine development often constitutes high-risk research for pharmaceutical companies. In helminthology in particular, the diminishing focus of research on vaccine development, the diminution of grant

funding, the difficulty to publish papers in prestigious journals, and the ensuing decline in the number of trainees in helminthes laboratories render the prospect of successful vaccines still far away.<sup>44,45</sup>

In the absence of vaccines, primary prevention depends largely on global public health measures and education. Prevention programs for schistosomiasis include education of the public in proper disposal of excreta to avoid contact with contaminated water. Infection with the oriental liver flukes *Opisthorchis* and *Clonorchis* can be prevented by refraining from eating raw or partially fermented freshwater fish. Educational campaigns in endemic areas of northeastern Thailand and elsewhere have had only limited success in dislodging long-ingrained traditional dietary practices. *H. pylori* infection appears to diminish in conjunction with improved household sanitation and hygiene. For HPV and HIV infection, “safe sex” practices may limit transmission (although this has been poorly studied for HPV), while for HCV, global testing of blood supplies and drug rehabilitation programs can control its spread. Only for EBV infection is primary prevention of infection unlikely to be attained by public health measures.

Secondary prevention, intended to impede the development of an existing infection to an advanced stage, is the rationale behind the Papanicolaou smear for signs of premalignant changes that may lead to cervical cancer. This cancer prevention strategy has proved an extraordinarily cost-effective method of health promotion. Where the Papanicolaou smear is widely employed, cervical cancer rates have plummeted. Some authors have also suggested that therapeutic vaccines may have a role to play in regression of cervical lesions related to HPV in humans.<sup>28</sup> Other secondary prevention strategies include case finding and chemotherapy of trematode and *H. pylori* infections. To date, however, very few prevention programs have been studied in terms of long-term efficacy or cost-effectiveness. Fendrick and colleagues evaluated how effective *Helicobacter pylori* treatment would need to be for it to be a cost-effective strategy for gastric cancer prevention (Fig. 12-2). In the United States, \$50,000 is considered a reasonable amount to pay for 1 year of life. Despite the low incidence of gastric cancer in the United States, screening 40-year-olds for *H. pylori* and treating all infected persons would only need to be 20% effective for it to be cost-effective. The screening and treatment strategy would be even more cost-effective in high-risk populations such as Japanese Americans.<sup>46</sup> Despite these promising numbers, results of the first randomized trial of *H. pylori* eradication to prevent gastric cancer have been discouraging, showing little difference between treatment and placebo groups.<sup>47</sup> However, methodological issues in this study left open to question whether *H. pylori* eradication may yet be a cost-effective strategy to prevent stomach cancer.

As mentioned previously, the epidemiology of carcinogenic pathogens is closely related to the social and economic characteristics of the human population that harbors them, and disease prevalence may change without biomedical intervention. Improvements in the storage, transportation, and processing of foods, and particularly the dissemination of refrigeration, appear to be responsible for the dramatic decline in gastric cancer in industrialized countries in recent decades. Knowledge of the transmission and ecology of *H. pylori* had nothing to do with this decrease. However,

**FIGURE 12-2** Example of sensitivity analysis. Risk reduction of cancer attributable to *H. pylori* eradication in a simulated cohort of men and women 40-years old serologically screened for *H. pylori* and treated when positive (no follow-up testing). Studies such as this one are the basis for ongoing secondary prevention studies to see if treatment of infection can prevent malignancy. (Adapted from Fendrick AM, Chernew ME, Hirth RA, et al: Clinical and economic effects of population-based *Helicobacter pylori* screening to prevent gastric cancer. Arch Intern Med 159[2]:142–148, 1999.)

known risk factors cannot always be easily altered. For example, early age at first intercourse and number of sexual partners are strongly associated with risk of cervical cancer, but are related to broad secular sociocultural trends. As technologies become more widespread, human behavior and activities evolve, and other emerging pathogens such as HIV appear, we can anticipate further changes in the epidemiology of infection-induced cancers.

## Chemotherapy of Parasitic Diseases

RICHARD D. PEARSON  
PETER F. WELLER  
RICHARD L. GUERRANT

### INTRODUCTION

A large number of drugs are used in the treatment of parasitic diseases, which is not surprising given the genetic diversity and varying life cycles of parasites. This chapter provides an overview of therapy based on phylogenetic and clinical factors. The treatment of helminth infections is summarized in sections on intestinal and systemic nematodes, trematodes, and cestodes. The therapy of protozoal infections follows and is divided into the treatment of malaria, luminal parasites, the kinetoplastida, and other systemic protozoal infections. A number of generalizations emerge from this approach that help in organizing an otherwise vast amount of information. In addition, the treatment of specific parasitic infections is addressed in detail. More complete discussions of the pharmacology and mechanisms of action of the antiparasitic drugs are found elsewhere.<sup>1,2</sup> Substantial additional information about indications, dosing, and toxicity is available in the Medical Letter on Drugs and Therapeutics, Drugs for parasitic infections ([www.medicalletter.org](http://www.medicalletter.org)),<sup>3</sup> as summarized in the tables in this chapter.

### TREATMENT OF INTESTINAL NEMATODES

The benzimidazoles, albendazole and mebendazole, have broad spectra of activities against intestinal nematodes, including *Ascaris lumbricoides*, *Trichuris trichiura*, *Ancylostoma duodenale*, *Necator americanus*, *Enterobius vermicularis*, and others (Table 13-1). Albendazole is particularly attractive because of its pharmacokinetics. It is effective in the treatment of most intestinal helminth infections when administered as a single dose, and it has been used successfully in mass treatment programs in developing countries. Pyrantel pamoate is active against the hookworms, *A. lumbricoides*, *E. vermicularis*, and some other intestinal nematodes, but it is not effective against *T. trichiura*. The benzimidazoles and pyrantel pamoate have replaced a number of older anthelmintics such as piperazine, which are more toxic or less effective but are still used in some developing areas. Ivermectin is recommended for the treatment of *Strongyloides stercoralis*. Thiabendazole, which is no longer manufactured in the United States, was previously the drug of choice, but it has substantial untoward effects. Some still use it in people with disseminated hyperinfection.

Albendazole has some activity against *S. stercoralis*, but even with high-dose prolonged therapy, failures may occur.

Albendazole, because of its broad spectrum of activity and favorable pharmacokinetics, has emerged as the drug of choice for the treatment of common intestinal nematode infections.<sup>4</sup> Mass treatment programs employing a single dose of albendazole to treat intestinal helminth infections have improved the nutritional status and fitness of malnourished children in Africa.<sup>5,6</sup> Albendazole is also effective in treating cutaneous larva migrans.<sup>7</sup> It is the drug of choice for echinococcal infections<sup>8,9</sup> and used for neurocysticercosis.<sup>10</sup> It is also used for the treatment of intestinal, ocular, and disseminated microsporidiosis due to *Encephalitozoon (Septata) intestinalis* and other microsporidia in patients with acquired immunodeficiency syndrome (AIDS), but not all microsporidia are susceptible.<sup>11</sup> Albendazole binds to tubulin in susceptible parasites, inhibits microtubule assembly, and decreases glucose absorption. It can also inhibit fumarate reductase in helminths.

Albendazole is poorly water soluble, but it is well absorbed when administered with a fatty meal. There is rapid first-pass metabolism in the liver to albendazole sulfoxide, which has excellent anthelmintic activity. The serum half-life of albendazole sulfoxide is 8 or 9 hours, and the concentration in cerebrospinal fluid (CSF) is 40% of that in serum. Concurrent administration of dexamethasone, which is frequently administered to patients being treated for neurocysticercosis to prevent cerebral edema, increases the serum levels by approximately 50%.<sup>12</sup> The concentration of albendazole sulfoxide in echinococcal cysts is approximately 25% of that in serum. Elimination of albendazole sulfoxide and other metabolites of albendazole is primarily through the kidney.

Albendazole is usually well tolerated when given as a single dose for the treatment of intestinal nematode infections, although some patients develop gastrointestinal discomfort or experience migration of adult *A. lumbricoides* from the nose or mouth or in the stool. Albendazole is embryotoxic in animals and contraindicated during pregnancy. High-dose, prolonged therapy for echinococcal disease is occasionally complicated by alopecia, reversible bone marrow suppression, or hepatocellular injury.

Mebendazole was widely used for the treatment of the common intestinal helminths prior to the introduction of albendazole.<sup>13</sup> It also kills the adults and has some activity against invasive larvae of *Trichinella spiralis*.<sup>14</sup> Mebendazole selectively binds to helminthic tubulin, blocks its assembly into microtubules, and inhibits glucose uptake, leading to depletion of glycogen stores and ultimately parasite death. Glucose metabolism is not affected in humans.

Mebendazole is only slightly soluble in water and is relatively poorly absorbed from the gastrointestinal tract,<sup>13</sup> which limits its effectiveness against tissue-dwelling helminths. The serum half-life of absorbed drug is 2.5 to 5.5 hours. It is metabolized in the liver and excreted in the urine. Mebendazole is relatively well tolerated in the doses used to treat intestinal helminths. Transient abdominal pain and diarrhea occur in a small number of recipients. Prolonged, high-dose therapy used in the treatment of echinococcal liver cysts has been associated with alopecia, hepatocellular injury, and transient bone marrow suppression with severe, but reversible, neutropenia. Mebendazole is contraindicated during pregnancy.

Thiabendazole has a broad spectrum of activity, but because of its toxicity, its systemic use has been limited to the treatment

**Table 13-1 Treatment of Nematode (Roundworm) Infections**

Infection	Drug	Adult Dosage	Pediatric Dosage
<b><i>Ancylostoma caninum</i></b> (Eosinophilic enterocolitis) Drug of choice:	Albendazole <sup>a</sup> or Mebendazole or Pyrantel pamoate <sup>a</sup> or Endoscopic removal	400 mg once 100 mg bid × 3 days 11 mg/kg (max. 1 g) × 3 days	400 mg once 100 mg bid × 3 days 11 mg/kg (max. 1 g) × 3 days

Trichinellosis ( <i>Trichinella spiralis</i> ) Drugs of choice:	Steroids for severe symptoms plus mebendazole <sup>a</sup> Albendazole <sup>a</sup>	200–400 mg tid × 3 days, then 400–500 mg tid × 10 days 400 mg bid × 8–14 days	200–400 mg tid × 3 days, then 400–500 mg tid × 10 days 400 mg bid × 8–14 days
Alternative: Trichostrongylus infection Drug of choice: Alternative:	Pyrantel pamoate <sup>a</sup> Mebendazole <sup>a</sup> or Albendazole <sup>a</sup>	11 mg/kg base once (max. 1 g) 100 mg bid × 3 days 400 mg once	11 mg/kg once (max. 1 g) 100 mg bid × 3 days 400 mg once

## Trichuriasis (*Trichuris trichiura*, whipworm)

Drug of choice:  
Alternative:

Mebendazole	100 mg bid × 3 days or 500 mg once	100 mg bid × 3 days or 500 mg once
Albendazole <sup>a</sup>	400 mg × 3 days	400 mg × 3 days
Ivermectin <sup>a</sup>	200 µg/kg/day × 3 days	200 µg/kg/day × 3 days
Albendazole <sup>a</sup>	400 mg bid × 5 days	400 mg bid × 5 days
Mebendazole <sup>a</sup>	100–200 mg bid × 5 days	100–200 mg bid × 5 days

## Visceral larva migrans (*Toxocariasis*)<sup>1a</sup>

Drug of choice:

<sup>a</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>b</sup>Most patients have a self-limited course and recover completely. Analgesics, corticosteroids, and careful removal of CSF at frequent intervals can relieve symptoms from increased intracranial pressure (Lo Re III V, Gluckman SJ. *Am J Med* 114:217, 2003). No anthelmintic drug is proven to be effective and some patients have worsened with therapy (Slom TJ, et al: *N Engl J Med* 346:668, 2002). In one report, however, mebendazole and a corticosteroid appeared to shorten the course of infection (Tsai, H-C, et al: *Am J Med* 111:109, 2001).

<sup>c</sup>The efficacy of anthelmintic therapy in humans has not been documented.

<sup>d</sup>Repiso Ortega A, et al: *Gastroenterol Hepatol* 26:341, 2003. Successful treatment of a patient with anisakiasis with albendazole has been reported (Moore DA, et al: *Lancet* 360:54, 2002).

<sup>e</sup>Nitazoxanide has activity against *Ascaris* and some other nematodes. It is FDA approved as a pediatric oral suspension for treatment of *Cryptosporidium* in immunocompetent children younger than 12 years old and for *Giardia* (Medical Letter 45:29, 2003). It may also be effective for mild to moderate amebiasis (Diaz E, et al: *Am J Trop Med Hyg* 68:384, 2003). Nitazoxanide is available in 500-mg tablets and an oral suspension; it should be taken with food.

<sup>f</sup>No drugs have been demonstrated to be effective. Albendazole 25 mg/kg/day × 20 days started as soon as possible (up to 3 days after possible infection) might prevent clinical disease and is recommended for children with known exposure (ingestion of racoon stool or contaminated soil) (MMWR 50:1153, 2002; Gavin PJ, Shulman, ST: *Pediatr Infect Dis* 22:651, 2003). Mebendazole, thiabendazole, levamisole, or ivermectin could be tried if albendazole were not available. Steroid therapy may be helpful, especially in eye and CNS infections. Ocular baylisascariasis has been treated successfully using laser photocoagulation therapy to destroy the intraretinal larvae.

<sup>g</sup>Treatment of choice is slow extraction of worm combined with wound care (Greenaway C: *CMAJ* 170:495, 2004). Ten days' treatment with metronidazole 250 mg tid in adults and 25 mg/kg/day in three doses in children is not curative but decreases inflammation and facilitates removal of the worm. Mebendazole 400–800 mg/day × 6 days has been reported to kill the worm directly.

<sup>h</sup>Since all family members are usually infected, treatment of the entire household is recommended by some experts.

<sup>i</sup>Most symptoms caused by adult worm. Single dose combination of albendazole (400 mg) with either ivermectin (200 mcg/kg) or diethylcarbamazine (6 mg/kg) is effective for reduction or suppression of *W. bancrofti* microfilaria but does not kill the adult forms (D Addiss et al, *Cochrane Database Syst Rev* 2004; CD003753).

<sup>j</sup>Antihistamines or corticosteroids may be required to decrease allergic reactions due to disintegration of microfilariae from treatment of filarial infections, especially those caused by *Loa loa*. Endosymbiotic *Wolbachia* bacteria may have a role in filarial development and host response, and may represent a new target for therapy. Treatment with doxycycline 100 or 200 mg/d × 4–6 wks in lymphatic filariasis and onchocerciasis has resulted in substantial loss of *Wolbachia* with subsequent block of microfilariae production and absence of microfilaria when followed for 24 months after treatment (A Hoerauf et al, *Med Microbiol Immunol* 2003; 192:211; A Hoerauf et al, *BMJ* 2003; 326:207).

<sup>k</sup>For patients with microfilaria in the blood, Medical Letter consultants would start with a lower dosage and scale up as indicated. Multi-dose regimens have been shown to provide more rapid reduction in microfilaria than single-dose diethylcarbamazine, but microfilaria levels are similar 6–12 mos after treatment (LD Andrade et al, *Trans R Soc Trop Med Hyg* 1995; 89:319; PE Simonsen et al, *Am J Trop Med Hyg* 1995; 53:267). A single dose of 6 mg/kg is used in endemic areas for mass treatment (J Figueredo-Silva et al, *Trans R Soc Trop Med Hyg* 1996; 90:192; J Noroes et al, *Trans R Soc Trop Med Hyg* 1997; 91:78).

<sup>l</sup>In heavy infections with *Loa loa*, rapid killing of microfilariae can provoke an encephalopathy. Apheresis has been reported to be effective in lowering microfilarial counts in patients heavily infected with *L. loa* (Ottesen EA: *Infect Dis Clin North Am* 7:619, 1993). Albendazole has also been used to reduce microfilaremia (Klion AD, et al: *J Infect Dis* 168:202, 1993; Kombila M et al: *Am J Trop Med Hyg* 58:458, 1998). Albendazole may be useful for treatment of loiasis when diethylcarbamazine is ineffective or cannot be used, but repeated courses may be necessary (Klion AD, et al: *Clin Infect Dis* 29:680, 1999). The use of ivermectin in loiasis has been associated with life-threatening encephalopathy. Diethylcarbamazine, 300 mg once/week, has been recommended for prevention of loiasis (Nutman TB, et al: *N Engl J Med* 319:752, 1988).

<sup>m</sup>Diethylcarbamazine has no effect. Ivermectin 200 µg/kg once, has been effective.

<sup>n</sup>Diethylcarbamazine is potentially curative due to activity against both adult worms and microfilariae. Ivermectin is only active against microfilariae.

<sup>o</sup>Relapse occurs and can be treated with diethylcarbamazine.

<sup>p</sup>Annual treatment with ivermectin, 150 µg/kg, can prevent blindness due to ocular onchocerciasis (Mabey D, et al: *Ophthalmology* 103:1001, 1996). Diethylcarbamazine should not be used for treatment of this disease.

<sup>q</sup>de Gorgolas M, et al: *J Travel Med* 10:358, 2003. All patients should be treated with a medication regardless of whether surgery is attempted.

<sup>r</sup>Eberhard ML, Busillo C: *Am J Trop Med Hyg* 61:51, 1999; Wilson ME, et al: *Clin Infect Dis* 32:1378, 2001.

<sup>s</sup>Albendazole or pyrantel pamoate may be effective (Ziem JB, et al: *Ann Trop Med Parasitol* 98:385, 2004).

<sup>t</sup>In immunocompromised patients or disseminated disease, it may be necessary to prolong or repeat therapy or to use other agents. Veterinary parenteral and enema formulations of ivermectin have been used in severely ill patients unable to take oral medications (Chiodini PL, et al: *Lancet* 355:43, 2000; Orem J, et al: *Clin Infect Dis* 37:152, 2003; Tarr PE: *Am J Trop Med Hyg* 68:453, 2003). The dose of thiabendazole recommended is likely to be toxic and may have to be decreased.

<sup>u</sup>Optimum duration of therapy is not known. Some Medical Letter consultants would treat for 20 days. For severe symptoms or eye involvement, corticosteroids can be used in addition.

Derived from the *Medical Letter on Drugs and Therapeutics*, Drugs for parasitic infections, www.medicalletter.org, August 2004. Recommendations that differ from those of the medical letter are marked with an asterisk.

of strongyloidiasis. It is also used topically for the treatment of cutaneous larva migrans.<sup>15</sup> Ivermectin is recommended for uncomplicated strongyloidiasis, although some experts consider thiabendazole the treatment of choice for those with disseminated hyperinfection. The mechanism of action of thiabendazole is thought to be similar to that of mebendazole and albendazole. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, are common. Other side effects include dizziness, tinnitus, and other neurological effects as well as elevated liver enzymes. It is contraindicated during pregnancy. Topically applied thiabendazole used in the treatment of cutaneous larva migrans is well tolerated.<sup>15</sup>

Pyrantel pamoate<sup>16</sup> is a depolarizing neuromuscular blocking agent that is active against *E. vermicularis*, the hookworms, and *A. lumbricoides*. It is poorly absorbed after oral administration. It is usually well tolerated. Some recipients experience transient gastrointestinal side effects or, less commonly, headache, drowsiness, insomnia, dizziness, or hypersensitivity reactions. It is not recommended for use during pregnancy. The muscles of susceptible nematodes undergo depolarization and an increase in spike discharge frequency that leads to a short period of calcium-dependent stimulation resulting in irreversible paralysis of the worms. They are subsequently expelled in the feces. Pyrantel also inhibits helminthic acetylcholinesterases. Piperazine, which paralyzes worms by causing hyperpolarization, and pyrantel are mutually antagonistic and should not be administered together.

Ivermectin, a macrocyclic lactone produced by *Streptomyces avermitilis*, has a broad spectrum of activity against helminths and arthropods. It is the drug of choice for the treatment of strongyloidiasis<sup>17,18</sup> and for onchocerciasis. Ivermectin is well absorbed after oral administration. It is highly protein bound, has a serum half-life of 12 hours, and accumulates in adipose tissue and in the liver. It is subject to enterohepatic recirculation and eliminated in the stool. Ivermectin activates the opening of gated-chloride channels that are found only in susceptible helminths and arthropods. The result is an influx of chloride ions and paralysis of the pharyngeal pumping mechanism of helminths. It is well tolerated when used for the treatment of strongyloidiasis. However, failures with ivermectin have been noted, leading to the use of multiple doses at weekly intervals in immunocompromised patients with disseminated disease or the use of other drugs. Ivermectin is widely used in veterinary practice for the treatment of nematodes such as the dog heart worm, *Dirofilaria immitis*.

## TREATMENT OF SYSTEMIC NEMATODES

Diethylcarbamazine is the drug of choice for several systemic filarial nematode infections, including those caused by *Wuchereria bancrofti*, *Brugia malayi*, *Brugia timori*, and *Loa loa*, and for people with tropical pulmonary eosinophilia<sup>19,20</sup> (see Table 13-1). Diethylcarbamazine is not directly toxic to microfilariae but promotes the host's killing of microfilariae of these species and also promotes damage or killing of adult worms. It can be used prophylactically to prevent *L. loa* infections in endemic areas. Diethylcarbamazine kills microfilariae of *Onchocerca volvulus*, but it is not used for the treatment of onchocerciasis because the rapid release of parasite antigens as well as lipopolysaccharide derived from filarial harbored *Wolbachia* endosymbionts often elicits severe systemic and ocular inflammatory reactions. Ivermectin, which is associated with much less severe reactions, is the drug of choice.

Diethylcarbamazine, a piperazine derivative, is well absorbed orally and has a half-life of 8 hours. The parent drug and its metabolites are excreted through the kidney. Side effects include those attributable directly to the drug and those that result from the release of parasite antigens and *Wolbachia* lipopolysaccharide. Side effects include nausea, vomiting, anorexia, headache, malaise, weakness, arthralgias, and, rarely, acute psychotic reactions. In patients with *W. bancrofti* or *B. malayi* infection, localized swelling or nodules may develop along lymphatics during treatment, or there may be transient lymphedema or hydrocele formation. Diethylcarbamazine is no longer used in patients with onchocerciasis because it can elicit the Mazzotti reaction, which is characterized by hypotension, pruritus, fever, tachycardia, wheezing, chorioretinitis, and uveitis secondary to the release of microfilarial antigens and *Wolbachia* lipopolysaccharide. Life-threatening encephalopathy has been reported in patients with heavy *L. loa* infections who received the drug.<sup>21</sup> Although the mechanism of diethylcarbamazine is uncertain, diethylcarbamazine enhances in vivo killing of filariae, resulting in their destruction by the host's immune system.

Ivermectin is the drug of choice for the treatment of onchocerciasis,<sup>22,23</sup> killing microfilariae in the skin and eye. It does not kill adult *O. volvulus*, but it decreases production of microfilariae. Retreatment is usually necessary at 6- to 12-month intervals. Ivermectin has activity against microfilaria of *W. bancrofti*, *B. malayi*, and *L. loa*, but it does not kill the adult worms. Profits from the use of ivermectin for the treatment of the dog heart worm, *D. immitis*, have permitted the manufacturer to provide the drug free to people with onchocerciasis in developing areas.

## TREATMENT OF CESTODES AND TREMATODES

Among the platyhelminths, praziquantel is active against adult cestodes (tapeworms) in the human intestinal tract (Table 13-2) and most trematodes that infect humans (Table 13-3).<sup>24,25</sup> The principal exception is *Fasciola hepatica*, which responds to the veterinary fasciolide, triclabendazole, and to bithionol.<sup>26,27</sup> Both albendazole and praziquantel kill cysticerci of *Taenia solium* in the central nervous system (CNS) and can be used in the treatment of neurocysticercosis.<sup>28,29</sup> Corticosteroids are often administered concomitantly to reduce the inflammatory response elicited by released cysticercal antigens and the increase in intracranial pressure that can result. The concurrent use of corticosteroids increases the CSF level of albendazole and decreases that of praziquantel. Albendazole is preferred by many for the treatment of neurocysticercosis. Prolonged albendazole therapy cures more than one-third of patients with *Echinococcus granulosus* cysts, and it is given to people with echinococcal cysts prior to and during percutaneous drainage procedures or surgery to prevent seeding of the peritoneum. It is also used for the suppression of inoperable *Echinococcus multilocularis* infections. The adverse effects of these anthelmintic drugs are summarized in Box 13-1.

Praziquantel is rapidly taken up by susceptible platyhelminths. Studies of the tapeworm *Hymenolepis diminuta* indicate that praziquantel causes blebs in the neck of the tapeworm and the release of calcium from endogenous stores, which results in paralysis and expulsion of the worm from the gastrointestinal tract.<sup>30</sup> In the case of schistosomes, praziquantel

Table 13-2 Treatment of Cestode (Tapeworm) Infections

Infection	Drug	Adult Dosage	Pediatric Dosage
<b>Adult (intestinal stage)</b>			
<i>Diphyllobothrium latum</i> (fish), <i>Taenia saginata</i> (beef), <i>Taenia solium</i> (pork), <i>Dipylidium caninum</i> (dog)			
Drug of choice:	Praziquantel <sup>a</sup>	5–10 mg/kg once	5–10 mg/kg once
Alternative:	Niclosamide	2 g once	50 mg/kg once
<i>Hymenolepis nana</i> (dwarf tapeworm)			
Drug of choice:	Praziquantel <sup>a</sup>	25 mg/kg once	25 mg/kg once
Alternative:	Nitazoxanide <sup>a,b</sup>	500 mg × 3 days <sup>c</sup>	1–3 yr: 100 mg bid × 3 days <sup>c</sup> 4–11 yr: 200 mg bid × 3 days <sup>c</sup>
<b>Larval (tissue stage)</b>			
<i>Echinococcus granulosus</i> (hydatid cyst)			
Drug of choice: <sup>d</sup>	Albendazole	400 mg bid × 1–6 mo	15 mg/kg/day (max. 800 mg) × 1–6 mo
<i>Echinococcus multilocularis</i>			
Treatment of choice:	See footnote <sup>e</sup>		
<i>Taenia solium</i> (Cysticercosis)			
Treatment of choice:	See footnote <sup>f</sup>		
Alternative:	Albendazole	400 mg bid × 8–30 days; can be repeated as necessary	15 mg/kg/day (max. 800 mg) in 2 doses × 8–30 days; can be repeated as necessary
	or Praziquantel <sup>a</sup>	50–100 mg/kg/day in 3 doses × 30 days	50–100 mg/kg/day in 3 doses × 30 days

<sup>a</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>b</sup>Nitazoxanide is FDA approved as a pediatric oral suspension for treatment of *Cryptosporidium* in immunocompetent children younger than 12 years old and for *Giardia* (Medical Letter 45:29, 2003). It may also be effective for mild to moderate amebiasis (Diaz E, et al: Am J Trop Med Hyg 68:384, 2003). Nitazoxanide is available in 500-mg tablets and an oral suspension; it should be taken with food.

<sup>c</sup>Juan JO, et al: Trans R Soc Trop Med Hyg 96:193, 2002.

<sup>d</sup>Patients may benefit from surgical resection or percutaneous drainage of cysts. Praziquantel is useful preoperatively or in case of spillage of cyst contents during surgery. Percutaneous aspiration–injection–reaspiration (PAIR) with ultrasound guidance plus albendazole therapy has been effective for management of hepatic hydatid cyst disease (Smego, RA, Jr et al: Clin Infect Dis 37:1073, 2003).

<sup>e</sup>Surgical excision is the only reliable means of cure. Reports have suggested that in nonresectable cases use of albendazole or mebendazole can stabilize and sometimes cure infection (Craig P: Curr Opin Infect Dis 16:437, 2003).

<sup>f</sup>Initial therapy for patients with inflamed parenchymal cysticercosis should focus on symptomatic treatment with antiseizure medication. Treatment of parenchymal cysticerci with albendazole or praziquantel is controversial. (Maguire, JM: N Engl J Med 350:215, 2004). Patients with live parenchymal cysts who have seizures should be treated with albendazole together with steroids (6 mg dexamethasone or 40–60 mg prednisone daily) and an antiseizure medication (Garcia HH, et al: N Engl J Med 350:249, 2004). Patients with subarachnoid cysts or giant cysts in the fissures should be treated for at least 30 days (Proaño JV, et al: N Engl J Med 345:879, 2001). Surgical intervention or CSF diversion are indicated for obstructive hydrocephalus; prednisone 40 mg/day may be given with surgery. Arachnoiditis, vasculitis, or cerebral edema are treated with prednisone 60 mg/day or dexamethasone 4–6 mg/day together with albendazole or praziquantel (White, AC Jr.: Annu Rev Med 51:187, 2000). Any cysticercoidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when corticosteroids are used. An ophthalmologic exam should always precede treatment to rule out intraocular cysts.

Alternative:	Oxamniquine <sup>g</sup>	15 mg/kg once <sup>h</sup>	20 mg/kg/day in 2 doses × 1 day <sup>h</sup>
<i>S. mekongi</i>			
Drug of choice:	Praziquantel	60 mg/kg/day in 3 doses × 1 day	60 mg/kg/day in 3 doses × 1 day

<sup>a</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>b</sup>Unlike infections with other flukes, *Fasciola hepatica* infections may not respond to praziquantel. Triclabendazole (Egaten, Novartis) may be safe and effective but data are limited (Graham CS, et al: Clin Infect Dis 33:1, 2001). It is available from Victoria Pharmacy, Zurich, Switzerland ([www.pharmaworld.com](http://www.pharmaworld.com); 41-1-211-24-32) and should be given with food for better absorption. A single study has found that nitazoxanide has limited efficacy for treating fascioliasis in adults and children (Favennec L, et al: Aliment Pharmacol Ther 17:265, 2003).

<sup>c</sup>Richter J, et al: Curr Treat Option Infect Dis 4:313, 2002.

<sup>d</sup>Nitazoxanide is FDA approved as a pediatric oral suspension for treatment of *Cryptosporidium* in immunocompetent children younger than 12 years old and for *Giardia* (Medical Letter, 45:29, 2003). It may also be effective for mild to moderate amebiasis (Diaz E, et al: Am J Trop Med Hyg 68:384, 2003). Nitazoxanide is available in 500-mg tablets and an oral suspension; it should be taken with food.

<sup>e</sup>MacLean JD, et al: Lancet 347:154, 1996.

<sup>f</sup>Triclabendazole may be effective in a dosage of 5 mg/kg once/day × 3 days or 10 mg/kg bid × 1 day (Calvopiña M, et al: Trans R Soc Trop Med Hyg 92:566, 1998).

<sup>g</sup>Oxamniquine has been effective in some areas in which praziquantel is less effective (Stelma FF, et al: J Infect Dis 176:304, 1997). Oxamniquine is contraindicated in pregnancy.

<sup>h</sup>In East Africa, the dose should be increased to 30 mg/kg, and in Egypt and South Africa to 30 mg/kg/day × 2 days. Some experts recommend 40–60 mg/kg over 2–3 days in all of Africa (Shekhar KC: Drugs 42:379, 1991).

Derived from *Medical Letter on Drugs and Therapeutics*, Drugs for parasitic infections, [www.medicalletter.org](http://www.medicalletter.org), August 2004.

### Box 13-1 Adverse Effects of Anthelmintic Drugs

#### Drugs Used for Nematode Infections

Albendazole (Albenza [GlaxoSmithKline])

**Occasional:** abdominal pain; migration of *Ascaris* through mouth and nose; reversible alopecia; increased serum transaminase activity

**Rare:** leukopenia; rash; renal toxicity

Diethylcarbamazine citrate USP\* (Hetrazan)

**Frequent:** severe allergic or febrile reactions in patients with microfilariae in the blood or skin; gastrointestinal disturbances

**Rare:** encephalopathy (with treatment of heavy *Loa loa* infection)

Ivermectin (Stromectol [Merck])

**Occasional:** Mazzotti-type reaction seen in onchocerciasis, including fever, pruritus, tender lymph nodes, headache, joint and bone pain

**Rare:** hypotension

Mebendazole (Vermox [McNeil])

**Occasional:** diarrhea, abdominal pain, migration of *Ascaris* through mouth and nose

**Rare:** leukopenia, agranulocytosis, hypospermia

Pyrantel pamoate (Antiminth [Pfizer])<sup>†</sup>

**Occasional:** gastrointestinal disturbances, headache, dizziness, rash, fever

#### Drugs Used for Cestode and Trematode Infections

Albendazole (Albenza [GlaxoSmithKline])—see above

Bithionol\* (Bitin [Tanabe, Japan])

**Frequent:** photosensitivity reactions, vomiting, diarrhea, abdominal pain, urticaria

**Rare:** leukoplakia, toxic hepatitis

Oxamniquine (Vansil [Pfizer])<sup>†</sup>

**Occasional:** headache, fever, dizziness, somnolence, nausea, diarrhea, rash, insomnia, hepatic enzyme changes, ECG changes, EEG changes, orange-red discoloration of urine

**Rare:** seizures, neuropsychiatric disturbances

Praziquantel (Biltricide [Bayer])

**Frequent:** abdominal pain, diarrhea, malaise, headache, dizziness

**Occasional:** sedation, fever, sweating, nausea, eosinophilia, fatigue

**Rare:** pruritus, rash, edema, hiccups

\*Available from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone (404) 639-3670; evenings, weekends, and holidays (404) 639-2888.

<sup>†</sup>Not available in the United States.

damages the tegument, resulting in intense vacuolation and increased permeability to calcium.<sup>31</sup> Adult schistosomes are paralyzed and translocated to the liver through the portal circulation. Sequestered antigens are exposed on the parasite's surface allowing for the binding of antibodies and phagocytes and immune destruction of the parasite.

Praziquantel is well absorbed after oral administration. There is extensive first-pass metabolism, and the metabolites, which are inactive, are excreted in the urine. Praziquantel is approximately 80% protein bound; the serum half-life is 4 to 6 hours. The concentration in the CSF is approximately 15% to 20% of that in plasma.<sup>32</sup> The concurrent administration of corticosteroids, which is often done in patients undergoing treatment for neurocysticercosis to decrease inflammation in the brain, reduces the CSF concentrations of praziquantel and may decrease its efficacy.

Praziquantel is frequently associated with mild, transient side effects, including headaches, lassitude, dizziness, nausea, vomiting, and abdominal discomfort, but these are seldom severe enough to interrupt therapy. Apparent untoward reactions due to the release of parasite antigens have been reported in patients treated for schistosomiasis and pulmonary paragonimiasis. Increased intracranial pressure resulting from the release of cysticercal antigens is a potentially life-threatening event in patients receiving praziquantel for neurocysticercosis, and corticosteroids are usually administered concurrently.<sup>33,34</sup> Praziquantel is contraindicated in people with cysticerci in the eye or spinal cord because of the deleterious consequences of local inflammatory reactions. The concurrent administration of cimetidine, ketoconazole, or miconazole can inhibit the metabolism of praziquantel and increase serum levels.

Niclosamide is active against adult tapeworms in the gastrointestinal tract.<sup>35</sup> It is very poorly absorbed, which limits its spectrum of activity to intestinal organisms. It is thought to uncouple oxidative phosphorylation in the mitochondria of adult cestodes, and it may also interfere with anaerobic metabolism. As the adult tapeworm dies, there is destruction of the scolex

and proximal portion with expulsion of the remainder of the worm in the feces.

Niclosamide is usually well tolerated, but it can cause mild gastrointestinal or systemic symptoms and, rarely, a rash. It kills adult *T. solium*, but the disintegration of the worm and the release of viable ova into the intestinal lumen raise the theoretical possibility of autoinfection. For this reason, many physicians prefer praziquantel for intestinal *T. solium* infection. When niclosamide is used, it is often followed by a purge to expedite removal of the worm. In the case of *Hymenolepis nana*, 5 to 7 days of niclosamide are needed to cure infection, whereas a single dose of praziquantel is effective, and it is consequently preferred.

Oxamniquine is an alternative to praziquantel for the treatment of *Schistosoma mansoni* infections.<sup>36</sup> Although the precise mechanism of its action is uncertain, it produces marked alterations in the tegument of adult schistosomes, but it does so over a period of days, in contrast to praziquantel, which acts in hours. Higher doses of oxamniquine are recommended for treatment in some areas of Egypt and equatorial Africa. Oxamniquine is well absorbed orally and has a half-life of 1.0 to 2.5 hours. The parent drug and its metabolites are cleared through the kidney and can produce an orange or red discoloration of the urine. Potential side effects include dizziness, drowsiness, skin rash, and gastrointestinal disturbances, including abdominal pain, diarrhea, nausea, vomiting, and loss of appetite. Seizures occur rarely. Oxamniquine is contraindicated in people with epilepsy and during pregnancy.

## TREATMENT OF SYSTEMIC PROTOZOAL INFECTIONS: MALARIA, BABESIOSIS, AND TOXOPLASMOSIS

### Malaria

The prophylaxis (Table 13-4; Box 13-2) and treatment of malaria (Table 13-5; see Box 13-2) are of great importance in

**Table 13-4** Drugs Used for Prevention of Malaria

Infection	Drug	Adult Dosage	Pediatric Dosage
<b>Malaria, prevention of<sup>a</sup></b>			
<b>Chloroquine-sensitive areas<sup>b</sup></b>

	Atovaquone/proguanil <sup>h,f</sup>	4 adult tabs daily × 3 days	<5 kg: not indicated 5–8 kg: 2 peds tabs once/day × 3 days 9–10 kg: 3 peds tabs once/day × 3 days 11–20 kg: 1 adult tab once/day × 3 days 21–30 kg: 2 adult tabs once/day × 3 days 31–40 kg: 3 adult tabs once/day × 3 days >40 kg: 4 adult tabs once/day × 3 days 30 mg/kg/d in 3 doses × 3–7 day <sup>p</sup>
	or Quinine sulfate plus doxycycline <sup>i,k</sup>	650 mg q8h × 3–7 day <sup>p</sup>	4 mg/kg/d in 2 doses × 7 day
	or Mefloquine <sup>h</sup>	100 mg bid × 7 day 750 mg followed 12 hrs later by 500 mg	15 mg/kg followed 12 hrs later by 10 mg/kg

<sup>a</sup>No drug regimen guarantees protection against malaria. If fever develops within 1 year (particularly within the first 2 months) after travel to malarious areas, travelers should be advised to seek medical attention. Insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis (Medical Letter 45:41, 2003). Malaria in pregnancy if particularly serious for both mother and fetus; therefore, prophylaxis is indicated if exposure cannot be avoided.

<sup>b</sup>Chloroquine-resistant *P. falciparum* occurs in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistant has been reported in Yemen, Oman, Saudi Arabia, and Iran). For treatment of multiple drug-resistant *P. falciparum* in Southeast Asia, especially Thailand, where resistance to mefloquine is frequent, atovaquone/proguanil, artesunate plus mefloquine, or artemether plus mefloquine may be used (Luxemburger JC, et al: Trans R Soc Trop Med Hyg 88:213, 1994; Karbwang J, et al: Trans R Soc Trop Med Hyg 89:296, 1995).

<sup>c</sup>In pregnancy, chloroquine prophylaxis has been used extensively and safely.

<sup>d</sup>For prevention of attack after departure from areas where *P. vivax* and *P. ovale* are endemic, which includes almost all areas where malaria is found (except Haiti), some experts prescribe in addition primaquine phosphate 30 mg base/day or, for children, 0.6 mg base/kg/day during the last 2 weeks of prophylaxis. Others prefer to avoid the toxicity of primaquine and rely on surveillance to detect cases when they occur, particularly when exposure was limited or doubtful. See below.

<sup>e</sup>Beginning 1 or 2 weeks before travel and continuing weekly for the duration of stay and for 4 weeks after leaving.

<sup>f</sup>Atovaquone plus proguanil is available as a fixed-dose combination tablet: adult tablets (Malarone; 250 mg atovaquone/100 mg proguanil) and pediatric tablets (Malarone Pediatric; 62.5 mg atovaquone/25 mg proguanil). To enhance absorption, it should be taken with food or a milky drink. Atovaquone/proguanil should not be given to pregnant women or patients with severe renal impairment (creatinine clearance <30 mL/min). There have been several isolated reports of resistance in *P. falciparum* in Africa (Schwartz E, et al: Clin Infect Dis 37:450, 2003; Farnert A, et al: BMJ 326:628, 2003).

<sup>g</sup>Beginning 1 or 2 days before travel and continuing for the duration of stay and for 1 week after leaving. In one study of malaria prophylaxis, atovaquone/proguanil was better tolerated than mefloquine in nonimmune travelers (Overbosch D, et al: Clin Infect Dis 33:1015, 2001).

<sup>h</sup>Adverse effects including nausea, vomiting, diarrhea, dizziness, disturbed sense of balance, toxic psychosis, and seizures can occur. Mefloquine should not be used for treatment of malaria in pregnancy unless there is no other treatment option because of increased risk for stillbirth Nosten F, et al: Clin Infect Dis 28:808, 1999). It should be avoided for treatment of malaria in people with active depression or with a history of psychosis or seizures and should be used with caution in people with psychiatric illness. Mefloquine can be given to patients taking  $\alpha$ -blockers if they do not have an underlying arrhythmia; it should not be used in patients with conduction abnormalities. Mefloquine should not be given together with quinine, quinidine, or halofantrine, and caution is required in using quinine, quinidine, or halofantrine to treat patients with malaria who have taken mefloquine for prophylaxis. Resistance to mefloquine has been reported in some areas, such as the Thailand–Myanmar and Thailand–Cambodia borders and in the Amazon basin, where 25 mg/kg should be used. In the United States, a 250-mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States, each 275-mg tablet contains 250 mg base.

<sup>i</sup>Mefloquine has not been approved for use during pregnancy. However, it has been reported to be safe for prophylactic use during the second or third trimester of pregnancy and possibly during early pregnancy as well (CDC Health Information for International Travel, 2003–2004, p 111; Smoak BL, et al: J Infect Dis 176:831, 1997). For pediatric doses less than half a tablet, it is advisable to have a pharmacist crush the tablet, estimate doses by weighing, and packing them in gelatin capsules. There are no data for use in children <5 kg, but based on dosages in other weight groups, a dose of 5 mg/kg can be used. Mefloquine is not recommended for patients with cardiac conduction abnormalities, and patients with a history of depression, seizures, psychosis, or psychiatric disorders should avoid mefloquine prophylaxis. Resistance to mefloquine has been reported in some areas, such as the Thailand–Myanmar and Thailand–Cambodia borders; in these areas, atovaquone/proguanil or doxycycline should be used for prophylaxis.

<sup>j</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>k</sup>Beginning 1 or 2 days before travel and continuing for the duration of stay and for 4 weeks after leaving. Use of tetracyclines is contraindicated in pregnancy and in children younger than 8 years old. Doxycycline can cause gastrointestinal disturbances, vaginal moniliasis, and photosensitivity reactions.

<sup>l</sup>Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G-6-PD deficiency before treatment. Primaquine should not be used during pregnancy.

<sup>m</sup>Studies have shown that daily primaquine beginning 1 day before departure and continued until 3–7 days after leaving the malaria area provides effective prophylaxis against chloroquine-resistant *P. falciparum* (Baird JK, et al: Clin Infect Dis 37:1659, 2003). Some studies have shown less efficacy against *P. vivax*. Nausea and abdominal pain can be diminished by taking with food.

<sup>n</sup>Proguanil (Paludrine–Wyeth Ayerst, Canada; AstraZeneca, United Kingdom), which is not available alone in the United States but is widely available in Canada and Europe, is recommended mainly for use in Africa south of Sahara. Prophylaxis is recommended during exposure and for 4 weeks afterwards. Proguanil has been used in pregnancy without evidence of toxicity (Phillips-Howard PA, Wood D: Drug Saf 14:131, 1996).

<sup>o</sup>A traveler can be given a treatment course of atovaquone/proguanil or pyrimethamine/sulfadoxine for presumptive self-treatment of febrile illness. This approach should be used only in very rare circumstances when a traveler cannot promptly receive medical care.

<sup>p</sup>In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 days.

Derived from Medical Letter on Drugs and Therapeutics, Drugs for parasitic infections, www.medicalletter.org, August 2004.

Table 13-5 Drugs Used for the Treatment of Malaria—cont'd

Infection	Drug	Adult Dosage	Pediatric Dosage
Prevention of relapses: <i>P. vivax</i> and <i>P. ovale</i> only			
Drug of choice:	Primaquine phosphate <sup>m</sup>	30 mg base/day × 14 days	0.6 mg base/kg/day × 14 days

<sup>a</sup>Chloroquine-resistant *P. falciparum* occurs in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistance has been reported in Yemen, Oman, Saudi Arabia, and Iran). For treatment of multiple drug-resistant *P. falciparum* in Southeast Asia, especially Thailand, where resistance to mefloquine is frequent, atovaquone/proguanil, artesunate plus mefloquine, or artemether plus mefloquine may be used (Luxemburger JC, et al: Trans R Soc Trop Med Hyg 88:213, 1994; Karbwang J, et al: Trans R Soc Trop Med Hyg 89:296, 1995).

<sup>b</sup>Uncomplicated or mild malaria may be treated with oral drugs.

<sup>c</sup>Atovaquone plus proguanil is available as a fixed-dose combination tablet: adult tablets (Malarone; 250 mg atovaquone/100 mg proguanil) and pediatric tablets (Malarone Pediatric; 62.5 mg atovaquone/25 mg proguanil). To enhance absorption, it should be taken with food or a milky drink. \* Some experts recommend dividing the daily dose and giving it bid to decrease the gastrointestinal side effects. Atovaquone/proguanil should not be given to pregnant women or patients with severe renal impairment (creatinine clearance <30 mL/min). There have been several isolated reports of resistance in *P. falciparum* in Africa (Schwartz E, et al: Clin Infect Dis 37:450, 2003; Farnert A, et al: BMJ 326:628, 2003).

<sup>d</sup>In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 days.

<sup>e</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>f</sup>Use of tetracyclines is contraindicated in pregnancy and in children younger than 8 years old.

<sup>g</sup>Fansidar is no longer recommended by the CDC nor used by most experts in North America because of widespread resistance and the potential for severe hypersensitivity reactions to sulfadoxine. Fansidar tablets contain 25 mg of pyrimethamine and 500 mg of sulfadoxine. The treatment dose is 3 tablets once for adults. For children it is ¼ tablet once for those <5 kg, ½ tablet once for 5–10 kg, 1 tablet once for 11–20 kg, 1½ tablet once for 21–30 kg, 2 tablets once for 31–40 kg, and 3 tablets once for >40 kg. Resistance to pyrimethamine-sulfadoxine has been reported from Southeast Asia, the Amazon basin, sub-Saharan Africa, Bangladesh, and Oceania.

<sup>h</sup>For use in pregnancy.

<sup>i</sup>Lell B, Kremsner PG: Antimicrob Agents Chemother 46:2315, 2002.

<sup>j</sup>At this dosage, adverse effects including nausea, vomiting, diarrhea, dizziness, disturbed sense of balance, toxic psychosis, and seizures can occur. Mefloquine should not be used for treatment of malaria in pregnancy unless there is no other treatment option because of increased risk for stillbirth (Nosten F, et al: Clin Infect Dis 28:808, 1999). It should be avoided for treatment of malaria in people with active depression or with a history of psychosis or seizures and should be used with caution in people with psychiatric illness. Mefloquine can be given to patients taking  $\alpha$ -blockers if they do not have an underlying arrhythmia; it should not be used in patients with conduction abnormalities. Mefloquine should not be given together with quinine, quinidine, or halofantrine, and caution is required in using quinine, quinidine, or halofantrine to treat patients with malaria who have taken mefloquine for prophylaxis. Resistance to mefloquine has been reported in some areas, such as the Thailand–Myanmar and Thailand–Cambodia borders and in the Amazon basin, where 25 mg/kg should be used. In the United States, a 250-mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States each 275-mg tablet contains 250 mg base.

<sup>k</sup>Nosten F, et al: Lancet 356:297, 2000; van Vugt, M: Clin Infect Dis 35:1498, 2002.

<sup>l</sup>*P. vivax* with decreased susceptibility to chloroquine is a significant problem in Papua New Guinea and Indonesia. There are also a few reports of resistance from Myanmar, India, the Solomon Islands, Vanuatu, Guyana, Brazil, Colombia, and Peru.

<sup>m</sup>Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Primaquine should not be used during pregnancy.

<sup>n</sup>If chloroquine phosphate is not available, hydroxychloroquine sulfate is as effective; 400 mg of hydroxychloroquine sulfate is equivalent to 500 mg of chloroquine phosphate.

<sup>o</sup>Exchange transfusion has been helpful for some patients with high-density (>10%) parasitemia, altered mental status, pulmonary edema, or renal complications (Miller KD, et al: N Engl J Med 321:65, 1989).

<sup>p</sup>Continuous ECG, blood pressure, and glucose monitoring is recommended, especially in pregnant women and young children. For problems with quinidine availability, call the manufacturers (Eli Lilly, 800-545-5979) or the CDC Malaria Hotline (770-488-7788). Quinidine may have greater antimalarial activity than quinine. The loading dose should be decreased or omitted in patients who have received quinine or mefloquine. If more than 48 hours of parenteral treatment is required, the quinine or quinidine dose should be reduced by 30% to 50%.

<sup>q</sup>Limited studies on efficacy except with *P. falciparum*; not FDA approved or available in the United States (Artemether-Quinine Meta-Analysis Study Group: Trans R Soc Trop Med Hyg 95:637, 2001; Marsh K: East Afr Med J 79:619, 2002).

Derived from *Medical Letter on Drugs and Therapeutics*, Drugs for parasitic infections, www.medicalletter.org, August 2004.

**Box 13-2** Adverse Effects of Antimalarial Drugs

Artemether\* (Artenam [Arenco, Belgium])

**Occasional:** neurologic toxicity, possible increase in length of coma, increased convulsions, prolongation of Q–Tc interval

Artesunate\* (Guilin No. 1 Factory, People's Republic of China)

**Occasional:** ataxia, slurred speech, neurologic toxicity, possible increase in length of coma, increased convulsions, prolongation of Q–Tc interval

Atovaquone (Mepron [GlaxoSmithKline]; Malarone [with proguanil [GlaxoSmithKline]])

**Occasional:** abdominal pain, nausea, vomiting, diarrhea, headache

Chloroquine HCl and chloroquine phosphate (Aralen [Sanofi], and others)

**Occasional:** pruritus; vomiting; headache; confusion; depigmentation of hair; skin eruptions; corneal opacity; weight loss; partial alopecia; extraocular muscle palsies; exacerbation of psoriasis, eczema, and other exfoliative dermatoses; myalgias; photophobia

**Rare:** irreversible retinal injury (especially when total dosage exceeds 100 g, discoloration of nails and mucous membranes, nerve-type deafness, peripheral neuropathy and myopathy, heart block, blood dyscrasias, hematemesis

Mefloquine (Lariam [Roche])

**Frequent:** vertigo, lightheadedness, nausea, other gastrointestinal disturbances, nightmares, visual disturbances, headache, insomnia

**Occasional:** confusion, psychological disturbance

**Rare:** psychosis, hypotension, convulsions, coma, paresthesias

Primaquine phosphate USP

**Frequent:** hemolytic anemia in glucose-6-phosphate dehydrogenase deficiency

**Occasional:** neutropenia, gastrointestinal disturbances, methemoglobinemia

**Rare:** CNS symptoms, hypertension, arrhythmias

Proguanil\* (Paludrine [Wyeth–Ayerst, Canada; AstraZeneca, United Kingdom], or with atovaquone, Malarone [GlaxoSmithKline])

**Occasional:** oral ulceration, hair loss, scaling of palms and soles, urticaria

**Rare:** hematuria (with large doses), vomiting, abdominal pain, diarrhea (with large doses), thrombocytopenia

Quinine dihydrochloride\* and sulfate (many manufacturers)

**Frequent:** cinchonism (tinnitus, headache, nausea, abdominal pain, visual disturbance)

**Occasional:** deafness, hemolytic anemia, other blood dyscrasias, photosensitivity reactions, hypoglycemia, arrhythmias, hypotension, drug fever

**Rare:** blindness, sudden death if injected too rapidly

\*Not available in the United States.

the tropics. The use of long-sleeved clothing, screens, and bed nets, the application of insect repellants with diethylmetatoluidide to exposed skin, and the use of permethrin or related residual insecticides on clothing and bed nets reduce the risk of Anopheline mosquito bites and transmission of malaria, but chemoprophylaxis is still necessary.<sup>37–39</sup>

Chloroquine is the drug of choice for the prophylaxis and treatment of malaria caused by chloroquine-sensitive *Plasmodium*

*vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium falciparum*.<sup>3,37–39</sup> Primaquine is used to prevent later relapses of *P. vivax* and *P. ovale*. It is the only currently available drug that is active against hypnozoites of those species.

*Plasmodium falciparum* and, to a lesser extent, *P. vivax* are notable among protozoa for their propensity to develop resistance to chemotherapeutic agents. Chloroquine resistance is widespread among *P. falciparum*. Only in Central America west of the Panama Canal, Haiti, adjacent areas of the Dominican Republic, and some areas of the Middle East can *P. falciparum* isolates be considered sensitive. Chloroquine-resistant *P. vivax* is well documented in Indonesia and some other areas,<sup>40</sup> but they are still focal and limited in number. Doxycycline, the fixed combination of atovaquone–proguanil (Malarone), or mefloquine can be used for chemoprophylaxis in areas where chloroquine-resistant *P. falciparum* or *P. vivax* are endemic.<sup>3,37–39</sup> The untoward effects of mefloquine, particularly its neuropsychiatric side effects, have been a source of increasing concern and limit its use.<sup>41</sup> Daily primaquine is another option in special circumstances. Quinine sulfate with tetracycline, treatment doses of mefloquine, or treatment doses of atovaquone–proguanil (in uncomplicated cases) are used for the therapy of acute chloroquine-resistant *P. falciparum* malaria. Halofantrine has been used for chloroquine-resistant malaria in Africa, but it is associated with prolonged QT interval and sudden death. It should be avoided unless no alternatives are available.

Resistance to mefloquine and quinine has emerged in rural areas of Thailand, elsewhere in Southeast Asia, and some other regions. Artesunate and other artemisinin derivatives, which have not been approved by the U.S. Food and Drug Administration (FDA), are used in Southeast Asia and some other areas of the world for the treatment of resistant *P. falciparum* infections. Specific recommendations for malaria prophylaxis and treatment depend on the infecting species and site of acquisition. The Centers for Disease Control and Prevention (CDC) provides recommendations for specific countries.<sup>37</sup> Drugs used for the treatment and prevention of malaria are summarized in Tables 13-4 and 13-5.

Chloroquine, a 4-aminoquinoline, remains the drug of choice for the prophylaxis and treatment of chloroquine-sensitive *P. vivax*, *P. ovale*, *P. malariae*, and *P. falciparum* malaria. Its mechanism of action has been extensively studied. It is concentrated in the hemoglobin-containing digestive vesicles of asexual intraerythrocytic parasites. Chloroquine inhibits the parasite's heme polymerase that incorporates ferriprotoporphyrin IX, which is potentially toxic to the parasite, into insoluble, nontoxic, crystalline hemozoin.<sup>42</sup> Chloroquine-resistant strains of *P. falciparum* actively transport chloroquine out of the intraparasitic compartment. Although this can be blocked by calcium channel inhibitors in vitro, chloroquine resistance has not been effectively reversed in humans. Hydroxychloroquine (Plaquenil) is also effective for prophylaxis against chloroquine-sensitive *Plasmodium* species.

Chloroquine has a bitter taste, but it is well absorbed from the gastrointestinal tract. The half-life, which varies, averages 4 days, permitting once-weekly administration for prophylaxis. Approximately half of the parent drug is excreted unchanged in the urine and the remainder is metabolized in the liver. Chloroquine is generally well tolerated when used at the doses recommended for the prophylaxis and treatment of

malaria. Side effects include headache, nausea, vomiting, blurred vision, dizziness, and fatigue. Some Africans and African Americans experience pruritus, which responds to antihistamines. Rare side effects include depigmentation of hair, exacerbation of psoriasis, blood dyscrasias, seizures, neuropsychiatric effects, and reactions in people with porphyria. Retinal damage has occurred in people receiving chloroquine at high doses for the treatment of rheumatologic disorders, but it has not been documented as a problem in people taking it weekly over many years for malaria prophylaxis.<sup>43</sup> Chloroquine has been used for chemoprophylaxis during pregnancy.

Children are more sensitive to the toxic effects of chloroquine than adults, and cardiopulmonary collapse and death have occurred following accidental overdoses and in adults attempting suicide. As little as 1 g of chloroquine can be fatal in children unless treatment is initiated with mechanical respiration, diazepam to control seizures, and blood pressure support.<sup>44</sup> An intravenous preparation of chloroquine is available outside the United States, but it must be given slowly and with great caution because of its propensity to produce respiratory depression, heart block, hypotension, cardiovascular collapse, and seizures.

Primaquine, an 8-aminoquinoline, is the only drug currently available that can eradicate hypnozoites of *P. vivax* and *P. ovale* in the liver. It is administered to people with *P. vivax* and *P. ovale* infections to prevent relapses. Relatively resistant strains of *P. vivax* have been reported from the Southwest Pacific, Southeast Asia, South America, and East Africa.<sup>45–47</sup> People infected with such strains often respond to higher doses of primaquine. Primaquine can also be used in special circumstances for prophylaxis against chloroquine-resistant *P. falciparum* and other forms of malaria, but recipients must be tested to ensure that they do not have glucose-6-phosphate dehydrogenase (G6PD) deficiency.<sup>48</sup> Primaquine plus clindamycin is an alternative to trimethoprim-sulfamethoxazole for the treatment of *Pneumocystis jiroveci* pneumonia in people who cannot tolerate sulfonamides.

Primaquine is well absorbed orally and rapidly converted to carboxyprimaquine, which has a half-life of approximately 7 days. The precise mechanism of action is unknown, but it is thought to interfere with mitochondrial function and possibly the transport of vesicles in the parasite. Primaquine is generally well tolerated, although some recipients experience abdominal cramps, epigastric distress, and nausea. The major concern is hemolysis in people with G6PD deficiency.<sup>49</sup> The G6PD status of the recipient should be determined before it is administered. Altered dosage schedules can be used in Africans with G6PD deficiency. Rarely, primaquine causes neutropenia, methemoglobinemia, hypertension, or arrhythmias. Primaquine is contraindicated during pregnancy and in breast-feeding mothers because life-threatening hemolysis may occur in the fetus or baby if they are G6PD deficient. Travelers should be warned not to give the drug to fellow travelers who have not been screened for G6PD deficiency.

Quinine sulfate, a cinchona alkaloid, is the oldest of the antimalarials.<sup>50</sup> With the exception of quinine-resistant *P. falciparum* strains in Thailand and adjacent areas of Southeast Asia, quinine is effective against all four *Plasmodium* species, including chloroquine-resistant *P. falciparum*. The mechanism of its action is unknown, but quinine is thought to act at the

level of the parasites' hemoglobin-containing digestive vesicle and may interfere with ferriprotoporphyrin IX metabolism.

Quinine has a very bitter taste. It is rapidly absorbed after oral administration and has a half-life of 16 to 18 hours in people with malaria. It is metabolized in the liver, and the native drug and its metabolites are excreted in the urine. Quinine has the poorest therapeutic-to-toxicity ratio of any antimalarial drug. The side effects, known collectively as cinchonism, include tinnitus, decreased hearing, headache, nausea, vomiting, dysphoria, and visual disturbances. They are dose related and reversible.

Quinine has also been associated with severe hypoglycemia in people with heavy *P. falciparum* infections due to the utilization of glucose by the parasites and release of insulin from the pancreas.<sup>51</sup> Hypoglycemia can be prevented or treated by the administration of intravenous glucose. Rare complications with quinine include massive hemolysis in patients with heavy *P. falciparum* infections resulting in hemoglobinuria and renal failure (blackwater fever), cutaneous hypersensitivity reactions, agranulocytosis, and hepatitis. Quinine can cause respiratory paralysis in people with myasthenia gravis. It stimulates uterine contractions and can produce abortions, but it has saved the lives of many pregnant women with *P. falciparum* malaria.

Quinidine gluconate, the stereoisomer of quinine, is recommended for the intravenous treatment of patients with acute malaria who cannot take quinine by mouth.<sup>52,53</sup> Quinidine gluconate is well-known for its role in the treatment of ventricular ectopy. Its side effects include prolongation of the Q-T interval, arrhythmias, and hypotension, particularly if it is infused too rapidly. People receiving intravenous quinidine should be monitored in an intensive care setting and changed to the oral quinine as soon as they can take medications by mouth. Where it is available, intravenous quinine dihydrochloride can be used if quinidine is not available. It, too, can produce myocardial depression, peripheral vascular collapse, respiratory depression, and death. Patients must be monitored closely during its infusion. Intravenous therapy with either drug should be terminated as soon as the patient is able to take oral drugs.

Mefloquine, a quinoline methanol compound derived from quinine, has been widely used for the prophylaxis and treatment of chloroquine-resistant *P. falciparum* malaria.<sup>54</sup> It is active against all four *Plasmodium* species, including those that are resistant to chloroquine. Mefloquine-resistant strains of *P. falciparum* are common in rural areas of Thailand and adjacent countries, and they have been reported from some other areas.

Mefloquine is available for oral administration only, and it is slowly and incompletely absorbed. It is 99% protein bound and has a variable half-life ranging from 6 to 23 days, with a mean of approximately 14 days. It is metabolized and excreted slowly through the bile and feces. Mefloquine appears to interfere with the food vacuoles of the intraerythrocytic asexual stage of the parasite.

Considerable attention has been paid to the untoward effects of mefloquine.<sup>41</sup> It is reasonably well tolerated in most recipients, although it can cause transient nausea, dizziness, vivid dreams, fatigue, and lassitude. Less common, but of substantial concern, are neuropsychiatric reactions that include anxiety, depression, acute psychosis, and seizures. Mefloquine is therefore contraindicated in people with a history of epilepsy

or psychiatric problems. It can depress atrial-ventricular conduction and should not be used by patients with cardiac conduction defects. Mefloquine may be used in people taking  $\beta$ -blockers if they have no underlying arrhythmias. Mefloquine also has antibacterial activity, and it can inactivate the live oral typhoid vaccine (*Salmonella typhi* Ty21a) if administered concurrently. Rare side effects include exfoliative erythroderma, agranulocytosis, and paresthesias. Mefloquine is not approved by the FDA for use during pregnancy or in children who weigh less than 15 kg, but it is used in situations in which the potential benefits are judged to outweigh the risks.<sup>55</sup>

Halofantrine, a 9-phenanthrenemethanol, has activity against the asexual, intraerythrocytic stages of chloroquine-sensitive and chloroquine-resistant strains of *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. It is not approved for use in the United States, but it is used in Africa. Halofantrine is variably absorbed after oral administration; higher levels are obtained if the drug is taken with a fatty meal. The half-life of the native drug is 1 or 2 days and that of its active metabolite is 3 to 5 days. It is excreted primarily in the feces. Halofantrine produces prolongation of the Q-T interval and has been associated with sudden death, presumably due to cardiac arrhythmias.<sup>56</sup>

Doxycycline taken daily provides effective prophylaxis against all *Plasmodium* species. Either tetracycline or doxycycline can be administered with quinine to treat acute chloroquine-resistant malaria. They do not act quickly enough to be used alone. The tetracyclines are well absorbed after oral administration, and they are generally well tolerated. They can produce gastrointestinal symptoms. Doxycycline can also cause severe esophagitis if it does not pass through to the stomach. Consequently, it should be taken with a full glass of water and the recipient should remain upright for 1 hour after ingestion. Other potential untoward effects include photosensitivity dermatitis, *Candida albicans* vaginitis, and antibiotic-associated colitis. Finally, tetracyclines should not be used in children younger than 8 years of age because of the potential for dental staining or in pregnant women.

Pyrimethamine alone or with sulfonamides has been used in the prevention and treatment of malaria, but resistance is now widespread. The two inhibit sequential steps in the folic acid metabolic pathway. Sulfonamides reduce the activity of dihydropteroate synthetase and reduce the binding of *p*-aminobenzoic acid to it. Pyrimethamine preferentially inhibits dihydrofolate reductase in susceptible parasites. Fansidar<sup>57</sup> is a fixed combination of pyrimethamine (25 mg) and sulfadoxine (500 mg), a long-acting sulfonamide with a half-life of 5 to 9 days. It has been associated with life-threatening cutaneous hypersensitivity reactions in people allergic to sulfonamides and is no longer marketed in the United States.

The most recent advance in the prevention and treatment of malaria is the fixed combination of atovaquone and proguanil (Malarone, adult tablets contain atovaquone 250 mg and proguanil 100 mg). It can be used for prophylaxis in areas with chloroquine-resistant *P. falciparum* and for the treatment of uncomplicated *P. falciparum* infections.<sup>58,59</sup> Malarone is better tolerated than mefloquine or doxycycline. Atovaquone used as a single drug also has activity against *Pneumocystis jiroveci*.<sup>60</sup>

Atovaquone is a highly lipophilic compound with low aqueous solubility. Administration with food enhances its absorption twofold. Plasma concentrations do not increase

proportionately with dose. Atovaquone is highly protein bound, with a half-life exceeding 60 hours. There is extensive enterohepatic cycling, and it is eventually excreted unchanged in the feces. Atovaquone selectively inhibits electron transport at the level of the cytochrome bc<sub>1</sub> complex, which results in collapse of the parasite's mitochondrial membrane potential. It also affects pyrimidine biosynthesis, which is obligatorily coupled to electron transport in *Plasmodium* through ubiquinone/ubiquinol. Resistance develops rapidly when atovaquone is used alone to treat malaria. It is generally well tolerated but can cause gastrointestinal side effects, including nausea, vomiting, and diarrhea, as well as skin rash and pruritus.

Proguanil is slowly absorbed after oral administration. The serum level falls to zero within 24 hours, so it must be taken daily for prophylaxis. Its triazine metabolite, cycloguanil, inhibits dihydrofolate reductase in susceptible *Plasmodium*. Resistance is well documented among *Plasmodium* species when the drug is used alone. Proguanil also acts synergistically with atovaquone to collapse mitochondrial membrane potential in *Plasmodium*. It is generally well tolerated. At higher doses it can cause nausea, vomiting, abdominal pain, and diarrhea. Hematological effects occur rarely.

The combination of atovaquone-proguanil (Malarone) is administered daily, starting 1 or 2 days before exposure, during travel, and for 7 days after the last potential exposure. It is generally well tolerated, but abdominal pain, nausea, vomiting, diarrhea, headache, pruritus, and rash may occur. Asymptomatic, transient elevations of liver enzymes have been observed with treatment doses of Malarone.

Artemisinin and its derivatives, which include artesunate, artemether, and arteether, are sesquiterpene lactones derived from the Chinese herbal medication for malaria, quinghaosu, which comes from the wormwood plant, *Artemisia annua*.<sup>61,62</sup> They are endoperoxide-containing compounds. In the presence of intraparasitic iron, they are thought to be converted into free radicals and other intermediates that alkylate specific malarial proteins and act rapidly to kill intraerythrocytic parasites. They are usually administered with a second antimalarial drug to prevent relapses. Although not licensed for use in the United States, artesunate and other artemisinin derivatives are widely used in Thailand and elsewhere to treat patients with mefloquine-resistant and/or quinine-resistant *P. falciparum* malaria.<sup>61,62</sup> The route of administration varies; some are administered orally, whereas others are given intravenously, intramuscularly, or by suppository. They are rapidly cleared from the circulation. Adverse effects are infrequent and mild. They include abdominal pain, diarrhea, and drug fever. Decreased reticulocytes and neutrophils and cerebellar dysfunction have been observed. Contact dermatitis has also been associated with sesquiterpene lactones. Neuropathic effects have been reported in dogs given chronic, high-dose therapy. The short half-life of the artemisinin derivatives and concern about potential neurotoxicity have precluded their use for malaria prophylaxis.

### Toxoplasmosis, Babesiosis, and Pneumocystis Pneumonia

Like *Plasmodium* species, *Toxoplasma gondii* and *Babesia* species are important pathogens of the phylum Apicomplexa. The medications used to treat them and their untoward effects are summarized in Box 13-3 and Table 13-6. They include

**Box 13-3** Adverse Effects of Drugs Used to Treat Other Protozoa

Atovaquone (Mepron [GlaxoSmithKline])

**Frequent:** rash, nausea**Occasional:** nausea, vomiting, diarrhea, rash

Dapsone (Jacobus)

**Frequent:** rash, transient headache, gastrointestinal irritation, anorexia, infectious mononucleosis–like syndrome**Occasional:** cyanosis due to methemoglobinemia and sulfhemoglobinemia; other blood dyscrasias, including hemolytic anemia; nephrotic syndrome; liver damage; peripheral neuropathy; hypersensitivity reactions; increased risk of lepra reactions; insomnia; irritability; uncoordinated speech; agitation; acute psychosis**Rare:** renal papillary necrosis, severe hypoalbuminemia, epidermal necrolysis, optic atrophy, agranulocytosis, neonatal hyperbilirubinemia after use in pregnancy

Pyrimethamine USP (Daraprim [GlaxoSmithKline])

**Occasional:** blood dyscrasias, folic acid deficiency**Rare:** rash, vomiting, convulsions, shock, possibly pulmonary eosinophilia, fatal cutaneous reactions with pyrimethamine-sulfadoxine (Fansidar)

Spiramycin (Rovamycin [Aventis])

**Occasional:** gastrointestinal disturbances**Rare:** allergic reactions

several of the antimalarial drugs discussed previously and the antibiotics clindamycin, azithromycin and spiramycin that act at the ribosomal level. Pyrimethamine and sulfadiazine are recommended for the treatment of toxoplasmosis. Clindamycin is an alternative to sulfadiazine for people with sulfonamide allergies. The macrolide, spiramycin, is recommended for the treatment of toxoplasmosis during pregnancy. Atovaquone plus azithromycin are now the first choice for babesiosis. Clindamycin and quinine are effective but more toxic. Trimethoprim-sulfamethoxazole, dapsone (a sulfone widely used in the treatment of leprosy), and several other drugs used for protozoal diseases are used in the treatment of *Pneumocystis jiroveci* as summarized in Table 13-6.

**TREATMENT OF INTESTINAL AND VAGINAL PROTOZOA**

Several major luminal pathogens, *Entamoeba histolytica*, *Giardia lamblia*, and *Trichomonas vaginalis*, which live in anaerobic conditions in the intestine or vagina, are susceptible to metronidazole or tinidazole.<sup>63,64</sup> The latter recently gained FDA approval (Table 13-7). The recommended treatment of these and other intestinal protozoal infections and the associated untoward effects are summarized in Tables 13-7 and Box 13-4, respectively. *Cryptosporidium*, which has been responsible for major water-borne epidemics in North America and elsewhere and is an important pathogen in people with AIDS, is resistant to most antimicrobial agents. Nitazoxanide has proven to be effective for cryptosporidiosis in immunocompetent children. Unfortunately, failures have been common in those with AIDS.<sup>65</sup> Nitazoxanide, which is available in oral formulation, is also approved for the treatment of giardiasis in children. Trimethoprim-sulfamethoxazole, which inhibits successive steps in the folic acid pathway, is effective

for the treatment of *Isospora belli* and *Cyclospora cayentanensis*. Ciprofloxacin, a fluoroquinolone antibiotic that acts on topoisomerase II, is an alternative. Albendazole is used to treat intestinal microsporidiosis due to *Encephalitozoon [Septata] intestinalis* and ocular and disseminated disease caused by some other microsporidia species.

Metronidazole, a nitroimidazole that is active only under anaerobic conditions, is used in the treatment of *E. histolytica*, *G. lamblia*, and *T. vaginalis* as well as for anaerobic bacterial diseases. It is activated by reduction of its 5-nitro group through a sequence of intermediate steps involving microbial electron transport proteins of low redox potential. It is concentrated in anaerobic organisms and serves as an electron sink.

Metronidazole is rapidly absorbed after oral administration and has a half-life of 8 hours. More than half of each dose is

**Box 13-4** Adverse Effects of Drugs Used in the Treatment of Luminal Protozoal Infections

Diloxanide furoate\* (Furamide [Boots, United Kingdom])

**Frequent:** flatulence**Occasional:** nausea, vomiting, diarrhea**Rare:** diplopia, dizziness, urticaria, pruritus

Furazolidone\* (Furoxone [Roberts])

**Frequent:** nausea, vomiting**Occasional:** allergic reactions, including pulmonary infiltration, hypotension, urticaria, fever, vesicular rash; hypoglycemia; headache**Rare:** hemolytic anemia in glucose-6-phosphate dehydrogenase deficiency and neonates, disulfiram-like reaction with alcohol, monoamine oxidase inhibitor interactions, polyneuritis

Iodoquinol (Yodoxin [Glenwood], others)

**Occasional:** rash, acne, slight enlargement of the thyroid gland, nausea, diarrhea, cramps, and pruritus**Rare:** optic neuritis, optic atrophy, loss of vision, peripheral neuropathy after prolonged use in high dosage (for months); iodine sensitivity

Metronidazole (Flagyl [Searle], others)

**Frequent:** nausea, headache, metallic taste, anorexia**Occasional:** vomiting, diarrhea, insomnia, weakness, stomatitis, vertigo, tinnitus, paresthesias, rash, dry mouth, dark urine, urethral burning, disulfiram-like reaction with alcohol, candidiasis**Rare:** seizures, encephalopathy, pseudomembranous colitis, ataxia, leukopenia, peripheral neuropathy, pancreatitis

Nitazoxanide (Alinia [Romark])

**Occasional:** gastrointestinal side effects

Ornidazole\* (Tiberal [Roche, France])

**Occasional:** dizziness, headache, gastrointestinal disturbances**Rare:** reversible peripheral neuropathy

Paromomycin (aminosidine; Humatin [Monarch]; Leshcutan\* [Teva, Israel])

**Frequent:** gastrointestinal disturbances with oral use**Occasional:** vestibular nerve damage (mainly auditory) and renal damage when aminosidine is given IV; vertigo; pancreatitis

Tinidazole (Tindamax [Presutti])

**Occasional:** metallic taste, nausea, vomiting, rash

Albendazole (see Box 13-1)

\*Not available in the United States.

<sup>a</sup>For treatment of keratitis caused by *Acanthamoeba*, concurrent topical use of 0.1% propanilide isethionate (Brolene) plus neomycin-polymyxin B-gramicidin ophthalmic solution has been successful (Hargrave SL, et al: Ophthalmology 106:952, 1999). In some European countries, propanilide is not available and hexamidine (Desmodine) has been used (Seal DV: Eye 17:893, 2003). In addition, 0.02% topical polyhexamethylene biguanide (PHMB) and/or chlorhexidine has been used successfully in a large number of patients (Tabin G, et al: Cornea 20:757, 2001; Wysesbeek YS, et al: Cornea 19:464, 2000). PHMB is available from Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773; www.leiterrx.com). The combination of chlorhexidine, natamycin (pimaricin), and debridement has also been successful (Kitagawa K, et al: Jpn J Ophthalmol 47:616, 2003).

<sup>b</sup>*Naegleria* infection has been treated successfully with intravenous and intrathecal use of both amphotericin B and miconazole plus rifampin and with amphotericin B, rifampin, and ornidazole (Seidel J, et al: N Engl J Med 306:346, 1982; Jain R, et al: Neuro India 50:470, 2002). Other reports of successful therapy are less well documented.

<sup>c</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>d</sup>Strains of *Acanthamoeba* isolated from fatal granulomatous amebic encephalitis are usually susceptible in vitro to pentamidine, ketoconazole, flucytosine, and (less so) to amphotericin B. Chronic *Acanthamoeba* meningitis has been successfully treated in two children with a combination of oral trimethoprim/sulfamethoxazole, rifampin, and ketoconazole (Singhal T, et al: Pediatr Infect Dis J 20:623, 2001) and in an AIDS patient with fluconazole, sulfadiazine, and pyrimethamine combined with surgical resection of the CNS lesion (Seijo Martinez M, et al: J Clin Microbiol 38:3892, 2000). Disseminated cutaneous infection in an immunocompromised patient has been treated successfully with IV pentamidine isethionate, topical chlorhexidine, and 2% ketoconazole cream, followed by oral itraconazole (Slater CA, et al: N Engl J Med 331:85, 1994).

<sup>e</sup>A free-living leptomycid ameba that causes subacute to fatal granulomatous CNS disease. Several cases of *Balamuthia* encephalitis have been successfully treated with flucytosine, pentamidine, fluconazole, and sulfadiazine plus either azithromycin or clanthromycin (phenothiazines were also used) combined with surgical resection of the CNS lesion (Deetz TR, et al: Clin Infect Dis 37:1304, 2003; Jung S, et al: Arch Pathol Lab Med 128:466, 2004).

<sup>f</sup>A free-living ameba not previously known to be pathogenic to humans. It has been successfully treated with azithromycin, IV pentamidine, itraconazole, and flucytosine combined with surgical resection of the CNS lesion (Gelman BB, et al: J Neuropathol Exp Neurol 62:990, 2003).

<sup>g</sup>Exchange transfusion has been used in severely ill patients and those with high (>10%) parasitemia (Hatcher JC, et al: Clin Infect Dis 32:1117, 2001). In patients who were not severely ill, combination therapy with atovaquone and azithromycin was as effective as clindamycin and quinine and may have been better tolerated (Krause PJ, et al: N Engl J Med 343:1454, 2000).

<sup>h</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>i</sup>Ocular lesions due to *E. hellem* in HIV-infected patients have responded to fumagillin eyedrops prepared from Fumidil-B (bicyclohexyl ammonium fumagillin) used to control a microsporidial disease of honey bees (Dresenhouse MG: Am J Ophthalmol 115:293, 1993), available from Leiter's Park Avenue Pharmacy. For lesions due to *V. corneae*, topical therapy is generally not effective and keratoplasty may be required (Davis RM, et al: Ophthalmology 97:953, 1990).

<sup>j</sup>Molina J-M, et al: J Infect Dis 171:245, 1995. There is no established treatment for *Pleiotophora*. For disseminated disease due to *Trachipleistophora* or *Brachiola*, itraconazole 400 mg PO once/day plus albendazole may also be tried (Coyle CM, et al: N Engl J Med 351:42, 2004).

<sup>k</sup>Pneumocystis has been reclassified as a fungus. In severe disease with room air PO<sub>2</sub> ≤ 70 mmHg or Aa gradient ≥35 mmHg, prednisone should also be used (Gagnon S, et al: N Engl J Med 323:1444, 1990; Caumes E, et al: Clin Infect Dis 18:319, 1994).

<sup>l</sup>Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Primaquine should not be used during pregnancy.

<sup>m</sup>Primary/secondary prophylaxis in patients with HIV can be discontinued after CD4 count increases to >200 × 10<sup>6</sup>/L for >3 months.

<sup>n</sup>An alternative trimethoprim/sulfamethoxazole regimen is one DS tab 3x/week. Weekly therapy with sulfadoxine 500 mg/pyrimethamine 25 mg/leucovorin 25 mg was effective PCP prophylaxis in liver transplant patients (Torre-Cisneros J, et al: Clin Infect Dis 29:771, 1999).

<sup>o</sup>Plus leucovorin 25 mg with each dose of pyrimethamine.

<sup>p</sup>In ocular toxoplasmosis with macular involvement, corticosteroids are recommended in addition to antiparasitic therapy for an anti-inflammatory effect.

<sup>q</sup>To treat CNS toxoplasmosis in HIV-infected patients, some clinicians have used pyrimethamine 50–100 mg/day (after a loading dose of 200 mg) with sulfadiazine and, when sulfonamide sensitivity developed, have given clindamycin 1.8–2.4 g/day in divided doses instead of the sulfonamide. Atovaquone plus pyrimethamine appears to be an effective alternative in sulfa-intolerant patients (Chirgwin K, et al: Clin Infect Dis 34:1243, 2002). Treatment is followed by chronic suppression with lower dosage regimens of the same drugs. For primary prophylaxis in HIV patients with <100 × 10<sup>6</sup>/L CD4 cells, trimethoprim-sulfamethoxazole, pyrimethamine with dapsone, or atovaquone with or without pyrimethamine can be used. Primary or secondary prophylaxis may be discontinued when the CD4 count increases to >200 × 10<sup>6</sup>/L for more than 3 months (USPHS/IDSA Guidelines for the Treatment of Opportunistic Infections in Adults and Adolescents with HIV, 2004).

<sup>r</sup>Women who develop toxoplasmosis during the first trimester of pregnancy can be treated with spiramycin (3–4 g/day). After the first trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. If transmission has occurred in utero, therapy with pyrimethamine and sulfadiazine should be started (Montoya JG, Liesenfeld O: Lancet 363:1965, 2004). Pyrimethamine is a potential teratogen and should be used only after the first trimester.

<sup>s</sup>Plus leucovorin 10–25 mg with each dose of pyrimethamine.

<sup>t</sup>Congenitally infected newborns should be treated with pyrimethamine every 2 or 3 days and a sulfonamide daily for about 1 year (Remington JS, Desmonts G: In Remington JS, Klein JO (eds), Infectious Disease of the Fetus and Newborn Infant, 5th ed. Philadelphia: Saunders, 2001, p. 290).

Table 13-7 Treatment of Luminal Protozoa

Infection	Drug	Adult Dosage	Pediatric Dosage
<b>Amebiasis (<i>Entamoeba histolytica</i>)</b> Asymptomatic Drug of choice:	Iodoquinol or Paromomycin Diloxanide furoate <sup>a</sup>	650 mg tid × 20 days 25–35 mg/kg/day in 3 doses × 7 days 500 mg tid × 10 days	30–40 mg/kg/day (max. 2 g) in 3 doses × 20 days 25–35 mg/kg/day in 3 doses × 7 days 20 mg/kg/day in 3 doses × 10 days
Alternative: Mild to moderate intestinal disease <sup>b</sup> Drug of choice: <sup>c</sup>	Metronidazole or Tinidazole <sup>d</sup>	500–750 mg tid × 7–10 days 2 g once daily × 3 days	35–50 mg/kg/day in 3 doses × 7–10 days 50 mg/kg/day (max. 2 g) in 1 dose × 3 days
<b>Severe intestinal and extraintestinal disease<sup>b</sup></b> Drug of choice:	Metronidazole or Tinidazole <sup>d</sup>	750 mg tid × 7–10 days 2 g once daily × 5 days	35–50 mg/kg/day in 3 doses × 7–10 days 50 mg/kg/day (max. 2 g) × 5 days
<b>Balantidiasis (<i>Balantidium coli</i>)</b> Drug of choice: Alternatives:	Tetracycline <sup>e,f</sup> Metronidazole <sup>e</sup> Iodoquinol <sup>e</sup>	500 mg qid × 10 days 750 mg tid × 5 days 650 mg tid × 20 days	40 mg/kg/day (max. 2 g) in 4 doses × 10 days 35–50 mg/kg/day in 3 doses × 5 days 40 mg/kg/day in 3 doses × 20 days
<b>Blastocystis hominis</b> infection Drug of choice:	See footnote <sup>g</sup>		
<b>Cryptosporidiosis (<i>Cryptosporidium</i>)</b> Non-HIV infected Drug of choice:	Nitazoxanide <sup>e</sup>	500 mg bid × 3 days <sup>e</sup>	1–3 yr: 100 mg bid × 3 days 4–11 yr: 200 mg bid × 3 days
<b>HIV infected</b> Drug of choice:	See footnote <sup>h</sup>		
<b>Cyclosporiasis (<i>Cyclospora cayentanensis</i>)</b> Drug of choice: <sup>i</sup>	Trimethoprim/sulfamethoxazole <sup>e</sup> (TMP)	TMP 160 mg/SMX 800 mg (1 DS tab) bid × 7–10 days	TMP 5 mg/kg, SMX 25 mg/kg bid × 7–10 days
<b><i>Dientamoeba fragilis</i> infection<sup>j</sup></b> Drug of choice:	Iodoquinol or Paromomycin <sup>e</sup> or Tetracycline <sup>e,f</sup> or Metronidazole	650 mg tid × 20 days 25–35 mg/kg/day in 3 doses × 7 days 500 mg qid × 10 days 500–750 mg tid × 10 days	30–40 mg/kg/day (max. 2 g) in 3 doses × 20 days 25–35 mg/kg/day in 3 doses × 7 days 40 mg/kg/day (max. 2 g) in 4 doses × 10 days 20–40 mg/kg/day in 3 doses × 10 days
<b>Giardiasis (<i>Giardia duodenalis</i>)</b> Drug of choice:	Metronidazole <sup>e</sup> Nitazoxanide <sup>e</sup>	250 mg tid × 5 days 500 mg bid × 3 days	15 mg/kg/day in 3 doses × 5 days 1–3 yr: 100 mg q12h × 3 days 4–11 yr: 200 mg q12h × 3 days
Alternatives: <sup>k</sup>	Tinidazole <sup>d</sup> Paromomycin <sup>e,l</sup> Furazolidone Quinacrine <sup>a</sup>	2 g once 25–35 mg/kg/day in 3 doses × 7 days 100 mg qid × 7–10 days 100 mg tid × 5 days	50 mg/kg once (max. 2 g) 25–35 mg/kg/day in 3 doses × 7 days 6 mg/kg/day in 4 doses × 7–10 days 2 mg/kg tid × 5 days (max. 300 mg/day)
<b>Isosporiasis (<i>Isospora belli</i>)</b> Drug of choice: <sup>m</sup>	Trimethoprim/sulfamethoxazole <sup>e</sup> (TMP)	TMP 160 mg/SMX 800 mg (1 DS tab) bid × 10 days	TMP 5 mg/kg, SMX 25 mg/kg bid × 10 days

Continued

Table 13-6 Treatment of Other Protozoal Diseases—Cont'd

Infection	Drug	Adult Dosage	Pediatric Dosage
Microsporidiosis			
Intestinal ( <i>Enterocytozoon bienersi</i> , <i>Encephalitozoon [Septata] intestinalis</i> )			
<i>E. bienersi</i> <sup>a</sup>			
Drug of choice:	Fumagillin	60 mg/day PO × 14 days	
<i>E. intestinalis</i>			
Drug of choice:	Albendazole <sup>c</sup>	400 mg bid × 21 days	
Trichomoniasis ( <i>Trichomonas vaginalis</i> )			
Drug of choice: <sup>a</sup>	Metronidazole or Tinidazole <sup>d</sup>	2 g once or 500 mg bid × 7 days 2 g once	15 mg/kg/day orally in 3 doses × 7 days 50 mg/kg once (max. 2 g)

<sup>a</sup>The drug is not available commercially, but as a service can be compounded by Panorama Compounding Pharmacy, 6744 Balboa Blvd, Van Nuys, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-6816).

<sup>b</sup>Treatment should be followed by a course of ivermectin or paromomycin in the dosage used to treat asymptomatic amebiasis.

<sup>c</sup>Nitazoxanide is FDA approved as a pediatric oral suspension for treatment of *Cryptosporidium* in immunocompetent children younger than 12 years old and for *Giardia* (Medical Letter 45:29, 2003). It may also be effective for mild to moderate amebiasis (Diaz E, et al: Am J Trop Med Hyg 68:384, 2003). Nitazoxanide is available in 500-mg tablets and an oral suspension; it should be taken with food.

<sup>d</sup>A nitro-imidazole similar to metronidazole, tinidazole was recently approved by the FDA and appears to be as effective and better tolerated than metronidazole. It should be taken with food to minimize GI adverse effects. For children and patients unable to take tablets, a pharmacist may crush the tablets and mix them with cherry syrup (Humco and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use. Ornidazole, a similar drug, is also used outside the United States.

<sup>e</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>f</sup>Use of tetracyclines is contraindicated in pregnancy and in children younger than 8 years old.

<sup>g</sup>Clinical significance of these organisms is controversial; metronidazole 750 mg tid × 10 days, ivermectin 650 mg tid × 20 days, or trimethoprim-sulfamethoxazole 1 DS tab bid × 7 days have been reported to be effective (Stenzel DJ, Borenstein PFL: Clin Microbiol Rev 9:563, 1996; Ok UZ, et al: Am J Gastroenterol 94:3245, 1999). Metronidazole resistance may be common (Hareesh K, et al: Trop Med Int Health 4:274, 1999). Nitazoxanide has been effective in children (Diaz E, et al: Am J Trop Med Hyg 68:384, 2003).

<sup>h</sup>Nitazoxanide has not consistently been shown to be superior to placebo in HIV-infected patients (Amadi B, et al: Lancet 360:1375, 2002). A small randomized, double-blind trial in symptomatic HIV-infected patients who were not receiving HAART found paromomycin similar to placebo (Hewitt RG, et al: Clin Infect Dis 31:1084, 2000).

<sup>i</sup>HIV-infected patients may need higher dosage and long-term maintenance (A Kansouzidou et al: J Trav Med 11:61, 2004).

<sup>j</sup>Norberg A, et al: Clin Microbiol Infect 9:65, 2003.

<sup>k</sup>Albendazole 400 mg daily × 5 days alone or in combination with metronidazole may also be effective (Hall A, Nahar Q: Trans R Soc Trop Med Hyg 87:84, 1993; Dutta AK, et al: Indian J Pediatr 61:689, 1994; Cacopardo B, et al: Clin Ter 146:761, 1995). Combination treatment with standard doses of metronidazole and quinacrine given for 3 weeks has been effective for a small number of refractory infections (Nash TE, et al: Clin Infect Dis, 33:22, 2001). In one study, nitazoxanide was used successfully in high doses to treat a case of *Giardia* resistant to metronidazole and albendazole (Abboud P, et al: Clin Infect Dis 32:1792, 2001).

<sup>l</sup>Not absorbed; may be useful for treatment of giardiasis in pregnancy.

<sup>m</sup>In immunocompetent patients usually a self-limited illness. Immunosuppressed patients may need higher doses, longer duration (TMP/SMX qid × 10 days, followed by bid × 3 weeks), and long-term maintenance. In sulfonamide-sensitive patients, pyrimethamine 50–75 mg daily in divided doses (plus leucovorin 10–25 mg/day) has been effective.

<sup>n</sup>Oral fumagillin (Sanofi Recherche, Gentilly, France) has been effective in treating *E. bienersi* (Molina J-M, et al: N Engl J Med 346:1963, 2002) but has been associated with thrombocytopenia. Highly active antiretroviral therapy (HAART) may lead to microbiologic and clinical response in HIV-infected patients with microsporidial diarrhea (USPHS/IDSA Guidelines for the Treatment of Opportunistic Infections in Adults and Adolescents with HIV, 2004). Octreotide (Sandostatin) has provided symptomatic relief in some patients with large-volume diarrhea.

<sup>o</sup>Sexual partners should be treated simultaneously. Metronidazole-resistant strains have been reported and can be treated with higher doses of metronidazole (2–4 g/day × 7–14 days) or with tinidazole (Hager WD: Sex Transm Dis 31:343, 2004).

Derived from the *Medical Letter on Drugs and Therapeutics*, Drugs for parasitic infections, www.medicalletter.org, August 2004.

metabolized in the liver. The metabolites and remaining parent drug are excreted in the urine. Nausea, vomiting, diarrhea, and a metallic taste are often associated with metronidazole use. They are less common with the lower doses (250 mg three times a day) recommended for the treatment of giardiasis than with the higher doses used for amebiasis (750 mg three times a day). Less common are headache, dizziness, vertigo, and numbness. Potentially severe disulfiram-like reactions occur in patients who ingest alcohol while taking metronidazole.

Tinidazole, another 5-nitroimidazole, has a similar mechanism of action and spectrum of activity. It has been widely used throughout the world and recently gained FDA approval for the treatment of giardiasis, intestinal amebiasis, and trichomoniasis in the United States. In comparison to metronidazole, it has a longer half-life, a shorter and less complicated dosing regimen, and fewer gastrointestinal side effects.

Since neither metronidazole nor tinidazole reliably eradicate cysts of *E. histolytica*, a luminal agent is used with them in people with amebiasis. The luminal agents include paromomycin, diloxanide furoate, and iodoquinol. Any of these agents can be used alone in people with asymptomatic cyst excretion.

Paromomycin (aminosidine), a poorly absorbed aminoglycoside, reaches high concentrations in the intestine and is effective against *E. histolytica* cysts.<sup>66,67</sup> It is generally well tolerated, although nausea, vomiting, abdominal pain, or diarrhea may occur. Absorbed paromomycin is excreted by the kidney and, like other aminoglycosides, is potentially ototoxic and nephrotoxic in people with renal failure.

Diloxanide furoate is also poorly absorbed and well tolerated. It is effective in killing *E. histolytica* cysts.<sup>68</sup> Mild gastrointestinal side effects may occur. It is not licensed for use in the United States.

Iodoquinol, a halogenated oxyquinoline, is another alternative. It, too, is poorly absorbed. Side effects include headache, diarrhea, nausea, vomiting, and abdominal pain. Less common are fever, itching, and seizures. Encephalopathy has also been reported.<sup>69</sup> Iodoquinol can cause iodine dermatitis, and its high iodine content can interfere with the results of thyroid function tests for months after therapy. A related compound, iodochlorohydroxyquin, gained notoriety in Japan as the cause of subacute myeloptic neuropathy. It caused serious optic nerve damage and peripheral neuropathy in recipients. It should be avoided.<sup>70</sup>

Nitazoxanide, a 5-nitrothiazole-salicylamide derivative, has a broad spectrum of activity against protozoa and helminths.<sup>71–74</sup> It is licensed in the United States for the treatment of giardiasis as well as cryptosporidiosis in immunocompetent children. It is formulated as a liquid. It is well absorbed orally and hydrolyzed to its active metabolite, tizoxanide, which undergoes conjugation to tizoxanide glucuronide. The parent compound is not detectable in serum. The maximum concentrations of the metabolites are observed in 1 to 4 hours. They are both excreted in urine and bile. Tizoxanide is highly protein bound. Although the mechanism of action is uncertain, tizoxanide may inhibit pyruvate:ferredoxin oxidoreductase enzyme-dependent electron transport reactions essential to the metabolism of anaerobic organisms.

Trimethoprim-sulfamethoxazole is the drug of choice for the treatment of enterocolitis due to *Isospora belli* and *Cyclospora cayetanensis*,<sup>3</sup> inhibiting two sequential steps in the folic acid pathway. Trimethoprim-sulfamethoxazole is generally well tolerated, but it can cause gastrointestinal symptoms as well as rash, fever, and other hypersensitivity responses in people

with sulfonamide allergies. In addition, the combination is associated with frequent side effects in people with AIDS, including rash, fever, and neutropenia.<sup>75</sup> Ciprofloxacin is an alternative for the treatment of isosporiasis and cyclosporiasis in sulfonamide-allergic patients.

## TREATMENT OF CHAGAS' DISEASE, AFRICAN TRYPANOSOMIASIS, AND LEISHMANIASIS

*Trypanosoma cruzi*, *Trypanosoma brucei rhodesiense*, and *Trypanosoma brucei gambiense* pose difficult therapeutic challenges. The drugs that are currently used to treat them are variably effective and often toxic (Box 13-5; Table 13-8).

### Box 13-5 Adverse Effects of Drugs Used to Treat Kinetoplastids

Benznidazole* (Rochagan [Roche, Brazil])
<b>Frequent:</b> allergic rash, dose-dependent polyneuropathy, gastrointestinal disturbances, psychic disturbances
Eflornithine* (Difluoromethylornithine, DFMO, Ornidyl [Aventis])
<b>Frequent:</b> anemia, leukopenia
<b>Occasional:</b> diarrhea, thrombocytopenia, seizures
<b>Rare:</b> hearing loss
Melarsoprol (Mel-B [Special])
<b>Frequent:</b> myocardial damage, albuminuria, hypertension, colic, Herxheimer-type reaction, encephalopathy, vomiting, peripheral neuropathy
<b>Rare:</b> shock
Miltefosine (Impavido [Zentaris, Germany])
<b>Frequent:</b> nausea; vomiting; diarrhea; "motion sickness"; elevations in liver enzymes, BUN, and creatinine
Nifurtimox (Lampit [Bayer, Germany])
<b>Frequent:</b> anorexia, vomiting, weight loss, loss of memory, sleep disorders, tremor, paresthesias, weakness, polyneuritis
<b>Rare:</b> convulsions, fever, pulmonary infiltrates and pleural effusion
Pentamidine isethionate (Pentam 300, NebuPent [Fujisawa])
<b>Frequent:</b> hypotension; hypoglycemia, may be followed by diabetes mellitus; vomiting; blood dyscrasias; renal damage; pain at injection site; gastrointestinal disturbances
<b>Occasional:</b> may aggravate diabetes; shock; hypocalcemia, liver damage; cardiotoxicity; delirium; rash
<b>Rare:</b> Herxheimer-type reaction, anaphylaxis, acute pancreatitis, hyperkalemia, ventricular arrhythmias
Pentavalent antimonials: meglumine antimonate* (Glucantime [Aventis, France]); sodium stibogluconate
(Pentostam [GlaxoSmithKline, United Kingdom])
<b>Frequent:</b> muscle and joint pain, fatigue, nausea, transaminase elevations, T-wave flattening or inversion, amylase elevation, pancreatitis
<b>Occasional:</b> weakness, abdominal pain, liver damage, bradycardia, leukopenia, thrombocytopenia, rash, vomiting
<b>Rare:</b> diarrhea, pruritus, myocardial damage, hemolytic anemia, renal damage, shock, sudden death
Suramin sodium (Germain[Bayer, Germany])
<b>Frequent:</b> vomiting, pruritus, urticaria, paresthesias, hyperesthesia of hands and feet, photophobia, peripheral neuropathy
<b>Occasional:</b> kidney damage, blood dyscrasias, shock, optic atrophy

\*Not available in the United States.

Table 13-8 Treatment of the Kinetoplastids: The *Leishmania* and *Trypanosomes*

Infection	Drug	Adult Dosage	Pediatric Dosage
<b>Leishmania infection</b>			
<b>Visceral<sup>a</sup></b>			
Drugs of choice:	Sodium stibogluconate or Meglumine antimonate or Amphotericin B <sup>c</sup>	20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 0.5–1 mg/kg IV daily or every second day for up to 8 wk	20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 0.5–1 mg/kg IV daily or every second day for up to 8 wk
Alternative: <sup>f</sup>	or Liposomal amphotericin B <sup>d</sup>  Pentamidine <sup>e</sup>	3 mg/kg/day IV (days 1–5) and 4 mg/kg IV or IM daily or every second day for 15–30 doses	3 mg/kg/day IV (days 1–5) and 3 mg/kg/day days 14 and 21 <sup>e</sup> 4 mg/kg IV or IM daily or every second day for 15–30 doses
	Miltefosine <sup>f</sup>		
<b>Cutaneous<sup>g</sup></b>			
Drugs of choice:	Sodium stibogluconate or Meglumine antimonate Pentamidine	20 mg Sb/kg/day IV or IM × 20 days <sup>b</sup> 20 mg Sb/kg/day IV or IM × 20 days <sup>b</sup> 2–3 mg/kg IV or IM daily or every second day × 4–7 doses <sup>i</sup>	20 mg Sb/kg/day IV or IM × 20 days <sup>b</sup> 20 mg Sb/kg/day IV or IM × 20 days <sup>b</sup> 2–3 mg/kg IV or IM daily or every second day × 4–7 doses <sup>i</sup>
Alternatives: <sup>h</sup>	or Paromomycin <sup>c,j</sup>	Topically 2×/day × 10–20 days	Topically 2×/day × 10–20 days
<b>Mucosal<sup>k</sup></b>			
Drugs of choice:	Sodium stibogluconate or Meglumine antimonate or Amphotericin B <sup>c</sup>	20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 0.5–1 mg/kg IV daily or every second day for up to 8 wk	20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 20 mg Sb/kg/day IV or IM × 28 days <sup>b</sup> 0.5–1 mg/kg IV daily or every second day for up to 8 wk
<b>Trypanosomiasis<sup>l</sup></b>			
<i>T. cruzi</i> (American trypanosomiasis, Chagas' disease)			
Drug of choice:	Benznidazole or Nifurtimox <sup>m</sup>	5–7 mg/kg/day in 2 divided doses × 30–90 days 8–10 mg/kg/day in 3–4 doses × 90–120 days	≤12 yr: 10 mg/kg/day in 2 doses × 30–90 days 1–10 yr: 15–20 mg/kg/day in 4 doses × 90 days 11–16 yr: 12.5–15 mg/kg/day in 4 doses × 90 days
<i>T. brucei gambiense</i> (West African trypanosomiasis, sleeping sickness)			
<b>Hemolymphatic stage</b>			
Drug of choice: <sup>n</sup>	Pentamidine isethionate <sup>c</sup>	4 mg/kg/day IM × 10 days	4 mg/kg/day IM × 10 days
Alternative:	Suramin	100–200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14 and 21	20 mg/kg on days 1, 3, 7, 14 and 21
<b>Late disease with CNS involvement</b>			
Drug of choice:	Melarsoprol <sup>o</sup> or Eflornithine <sup>p</sup>	2.2 mg/kg/day × 10 days 400 mg/kg/day in 4 doses × 14 days	2.2 mg/kg/day × 10 days 400 mg/kg/day in 4 doses × 14 days

# *T. b. rhodesiense* (East African trypanosomiasis, sleeping sickness)

## Hemolymphatic stage

Drug of choice: Suramin

100–200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14 and 21

20 mg/kg on days 1, 3, 7, 14, and 21

## Late disease with CNS involvement

Drug of choice: Melarsoprol<sup>b</sup>

2–3.6 mg/kg/day × 3 days; after 7 days  
3.6 mg/kg/day × 3 days; repeat again after 7 days

2–3.6 mg/kg/day × 3 days; after 7 days  
3.6 mg/kg/day × 3 days; repeat again after 7 days

<sup>a</sup>Visceral infection is most commonly due to the Old World species *L. donovani* (kala-azar) and *L. infantum* and the New World species *L. chagasi*. Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired.

<sup>b</sup>May be repeated or continued; a longer duration may be needed for some patients (Herwaldt BL. Lancet 354:1191, 1999).

<sup>c</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>d</sup>Three lipid formulations of amphotericin B have been used for treatment of visceral leishmaniasis (Meyerhoff A: Clin Infect Dis 28:42, 1999). Amphotericin B lipid complex (Abelcet) and amphotericin B cholesteryl sulfate (Amphotec) have also been used with good results but are considered investigational for this condition by the FDA.

<sup>e</sup>The FDA-approved dosage regimen for immunocompromised patients (e.g., HIV infected) is 4 mg/kg/day (days 1–5) and 4 mg/kg/day on days 10, 17, 24, 31, and 38. The relapse rate is high; maintenance therapy may be indicated, but there is no consensus as to dosage or duration.

<sup>f</sup>For treatment of kala-azar in adults in India, oral miltefosine 100 mg/day (~2.5 mg/kg/day) for 3 or 4 weeks was 97% effective after 6 months, (Jha TK, et al: N Engl J Med 341:1795, 1999; Sangraula H, et al: J Assoc Physicians India 51:686, 2003). Gastrointestinal adverse effects are common, and the drug is contraindicated in pregnancy. The dose of miltefosine in an open-label trial in children in India was 2.5 mg/kg/day × 28 days (Bhattacharya SK, et al: Clin Infect Dis 38:217, 2004). Miltefosine (Impavido) is available from the manufacturer (Zentaris, Frankfurt, Germany; Impavido@zentaris.de).

<sup>g</sup>Cutaneous infection is most commonly due to the Old World species *L. major* and *L. tropica* and the New World species *L. mexicana*, *L. (Viannia) braziliensis*, and others. Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired.

<sup>h</sup>In a placebo-controlled trial in patients 12 years old and older, oral miltefosine was effective for the treatment of cutaneous leishmaniasis due to *L. (V) panamensis* in Colombia but not *L. (V) braziliensis* in Guatemala at a dosage of about 2.5 mg/kg/day for 28 days. "Motion sickness," nausea, headache, and increased creatinine were the most frequent adverse effects (Soto J, et al: Clin Infect Dis 38:1266, 2004). For treatment of *L. major* cutaneous lesions, a study in Saudi Arabia found that oral fluconazole, 200 mg once/day × 6 weeks, appeared to speed healing (Alrajhi AA, et al: N Engl J Med 346:891, 2002).

<sup>i</sup>At this dosage pentamidine has been effective against leishmaniasis in Colombia, where the likely organism was *L. (V) panamensis* (Soto-Mancipe J, et al: Clin Infect Dis 16:417, 1993; Soto J, et al: Am J Trop Med Hyg 50:107, 1994); its effect against other species is not well established.

<sup>j</sup>Topical paromomycin should be used only in geographic regions where cutaneous leishmaniasis species have low potential for mucosal spread. A formulation of 15% paromomycin/12% methylbenzethonium chloride (Leshcutan) in soft white paraffin for topical use has been reported to be partially effective in some patients against cutaneous leishmaniasis due to *L. major* in Israel and against *L. mexicana* and *L. (V) braziliensis* in Guatemala, where mucosal spread is very rare (Arana BA, et al: Am J Trop Med Hyg 65:466, 2001). The methylbenzethonium is irritating to the skin; lesions may worsen before they improve.

<sup>k</sup>Mucosal infection is most commonly due to the New World species *L. (V) braziliensis*, *L. (V) panamensis*, or *L. (V) guyanensis*. Treatment duration may vary based on symptoms, host immune status, species, and area of the world where infection was acquired.

<sup>l</sup>Barrett MP et al: Lancet 362:1469, 2003.

<sup>m</sup>The addition of gamma interferon to nifurtimox for 20 days in experimental animals and in a limited number of patients appears to shorten the acute phase of Chagas' disease (McCabe RE, et al: J Infect Dis 163:912, 1991).

<sup>n</sup>For treatment of *T. b. gambiense*, pentamidine and suramin have equal efficacy but pentamidine is better tolerated.

<sup>o</sup>In frail patients, begin with as little as 18 mg and increase the dose progressively. Pretreatment with suramin has been advocated for debilitated patients. Corticosteroids have been used to prevent arsenical encephalopathy (Pepin J, et al: Trans R Soc Trop Med Hyg 89:92, 1995). Up to 20% of patients with *T. b. gambiense* fail to respond to melarsoprol (Barrett MP: Lancet 353:1113, 1999).

<sup>p</sup>Eflornithine is highly effective in *T. b. gambiense* but not against *T. b. rhodesiense* infections. It is available in limited supply only from WHO and CDC.

Derived from the *Medical Letter on Drugs and Therapeutics*, Drugs for parasitic infections, www.medicalletter.org, August 2004.

Nifurtimox and benznidazole are used for Chagas' disease. Suramin, pentamidine, and melarsoprol are used for human African trypanosomiasis (sleeping sickness). The development of eflornithine for the treatment of *T. brucei gambiense* was a major advance,<sup>76,77</sup> but the quantity of drug needed for treatment and the cost have curtailed its use. Supplies are very limited worldwide. Stibogluconate sodium, meglumine antimoniate, liposomal amphotericin B, amphotericin B deoxycholate, miltefosine, and several other drugs are used for the treatment of leishmaniasis.

Nifurtimox, a nitrofurantoin, is used for the treatment of Chagas' disease in the United States.<sup>78,79</sup> Although it is no longer in production, it is available through the CDC. Nifurtimox lowers mortality due to myocarditis and meningoencephalitis and shortens the duration of symptoms in acute Chagas' disease. It is administered daily for a period of 90 to 120 days. Side effects occur in more than half of those treated and include anorexia, vomiting, abdominal pain, weight loss, sleep disorders, paresthesias, weakness, and polyneuritis. These untoward effects are usually reversible when the drug is stopped, but they often pose a therapeutic dilemma given the long duration of treatment. Seizures, rash, and neutropenia occur rarely.

Benznidazole, a nitroimidazole, is used in the treatment of Chagas' disease in Latin America.<sup>80,81</sup> It is administered for 30 to 90 days. It is frequently associated with skin reactions, dose-dependent polyneuropathy, gastrointestinal symptoms, bone marrow suppression, and psychiatric side effects. Benznidazole has been recommended for the treatment of children and young adults with indeterminate phase *T. cruzi* infection. It may cure as many as two-thirds of those treated. Treatment with neither benznidazole nor nifurtimox reverses the manifestations of chronic Chagas' disease.

Suramin, a very toxic drug is used for the treatment of the hemolymphatic stage of African trypanosomiasis.<sup>82,83</sup> It must be administered intravenously. Suramin is frequently associated with nausea, vomiting, urticarial eruptions, paresthesias, hyperesthesias, and peripheral neuropathy. Less frequent side effects are renal damage, blood dyscrasias, loss of consciousness, and shock.

Pentamidine isethionate, a diamidine, is used for the treatment of the hemolymphatic stage of *T. brucei gambiense* infection.<sup>84,85</sup> It is an alternative to pentavalent antimony-containing drugs for the treatment of leishmaniasis, but toxicity has limited its use. Pentamidine can also be used for pneumocystis pneumonia in people who cannot tolerate trimethoprim-sulfamethoxazole.<sup>86</sup> Finally, aerosolized pentamidine can be used for prophylaxis against *P. jiroveci* in people with AIDS, but when administered in this way, it does not prevent infection in organs other than the lungs, and there are problems associated with its administration and the venting of exhaled drug.

Pentamidine is usually administered intravenously. Intramuscular injections are associated with inflammation and sterile abscesses at the site of inoculation. It is not absorbed orally. The mechanism of action is not known, but it may interact with the parasite's DNA. Side effects are common and include gastrointestinal complaints, dizziness, tachycardia, flushing, and hypotension if the drug is infused too rapidly. Renal function is impaired transiently in as many as one-fourth of recipients. A major concern is hypoglycemia that results from the release of insulin from damaged pancreatic beta cells. Patients with higher pentamidine levels appear

to be at greater risk. Fatalities have been reported during and after therapy. The development of insulin-dependent diabetes mellitus is an important long-term adverse effect.

Melarsoprol, a trivalent arsenical, is administered intravenously for the treatment of African trypanosomiasis with CNS involvement.<sup>82,83</sup> Fever, abdominal pain, vomiting, arthralgias, myocardial toxicity, hypertension, albuminuria, and peripheral neuropathy are common.<sup>82,83</sup> More important, approximately 6% of recipients develop allergic encephalitis, which is characterized by headache, dizziness, mental dullness, confusion, ataxia, obtundation, and seizures; overall, 4% of patients die as a consequence.<sup>87,88</sup> Cardiovascular collapse is a rare complication.

Eflornithine (difluoromethylornithine), the "resurrection drug," is effective against the hemolymphatic and CNS stages of *T. brucei gambiense* infection.<sup>89-91</sup> It is an enzyme-activated, irreversible inhibitor of ornithine decarboxylase, an important enzyme in the polyamine pathway. It does not have activity against *T. brucei rhodesiense*. Unfortunately, eflornithine is costly; those affected by the disease live in impoverished areas, and it has been difficult to find a manufacturer for the drug. Supplies are very limited.

Eflornithine can be administered orally or intravenously. The ratio of the level in CSF to serum ranges from 0.09 to 0.45; the ratio is highest in patients who have the most severe CNS involvement. Most of the drug is excreted in the urine. In contrast to the other drugs used to treat African trypanosomiasis, eflornithine is relatively well tolerated. Flatulence, nausea, vomiting, and diarrhea can occur, but they are transient. Some recipients develop reversible anemia, thrombocytopenia, or neutropenia. Diplopia, dizziness, or hypersensitivity reactions occur rarely.

Sodium stibogluconate and meglumine antimoniate, pentavalent antimony-containing drugs, have been widely used for the treatment of leishmaniasis.<sup>92-94</sup> Sodium stibogluconate is available through the CDC in the United States and in Britain, whereas meglumine antimoniate is used in French-speaking areas and in Latin America. They are administered intravenously or intramuscularly. Although the bioavailability can vary among lots, sodium stibogluconate and meglumine antimoniate appear to be of comparable efficacy and toxic when administered on the basis of their pentavalent antimony content.

They are administered at a dose of 20 mg of pentavalent antimony per kilogram body weight per day for 20 to 28 days depending on the clinical syndrome and infecting *Leishmania* species. Their mechanism of action is uncertain. Although most patients are able to complete a full course of therapy, side effects are common and include nausea, vomiting, abdominal pain, anorexia, myalgias, arthralgias, headache, and malaise. Chemical pancreatitis is observed in many patients, and severe pancreatitis occurs in some. It is particularly common in people with renal failure. Nonspecific ST-T wave changes are common. Less frequent side effects are elevated liver enzymes, bradycardia, leukopenia, thrombocytopenia, and anemia. Renal toxicity, myocardial damage, and shock are rare. Sudden death, possibly from arrhythmia, has been reported in people receiving more than the recommended dose.

Amphotericin B deoxycholate, well-known as an antifungal agent, is an effective alternative to pentavalent antimonials for the treatment of visceral and mucosal leishmaniasis.<sup>95,96</sup>

It is administered intravenously over a prolonged period of time. Amphotericin B binds to sterols, such as ergosterol, and is thought to damage the cytoplasmic membrane of leishmania much as it does the membranes of susceptible fungi. Untoward effects including fever, chills, malaise, nausea, anorexia, and vomiting accompany administration. Both acute and chronic nephrotoxicity and resulting electrolyte abnormalities are common.

Liposomal amphotericin B (AmBisome) is the only drug approved for the treatment of visceral leishmaniasis in the United States.<sup>97,98</sup> Direct delivery of drug to the reticuloendothelial system by liposomes is theoretically attractive since leishmanias reside in mononuclear phagocytes. Liposomal amphotericin B is relatively well tolerated in comparison to amphotericin B deoxycholate. Other lipid-associated amphotericin B preparations also appear to be effective but have been less extensively studied. Although liposomal amphotericin B is considered the drug of choice for the treatment of visceral leishmaniasis in the United States and other industrialized countries, the high cost has limited its use in the rest of the world. Therapeutic failures have been reported in people with cutaneous leishmaniasis treated with liposomal amphotericin B.

Miltefosine (hexadecylphosphocholine) is the only orally administered drug with activity against *Leishmania* species. It is currently used in India, where resistance to pentavalent antimony is common, for the treatment of visceral leishmaniasis.<sup>99–101</sup> Preliminary studies suggest that miltefosine may also be useful in the treatment of cutaneous leishmaniasis but at higher doses than those used for visceral leishmaniasis.<sup>102</sup> Further studies are needed to define the role of miltefosine in the treatment of visceral leishmaniasis in areas of the world other than India and in the treatment of cutaneous and mucosal leishmaniasis.

Miltefosine was developed initially as an antineoplastic agent. Although the precise mechanism of action is uncertain, it is known to interact with membrane constituents. It affects cell signaling pathways by inhibiting phosphokinase C and protein kinase C. It also interferes with the synthesis of glycosylphosphatidylinositol membrane anchors, which are important in leishmania and related kinetoplastids. Miltefosine is relatively well tolerated, but nausea, vomiting, and motion sickness may occur. Elevations of transaminases, BUN, and creatinine have been noted but usually resolve with continuation of the drug. The side effects seldom result in premature termination of therapy in patients treated for visceral leishmaniasis.

A number of other drugs have been used in the treatment of leishmaniasis. They include the imidazole antifungals, ketoconazole,<sup>103</sup> itraconazole,<sup>104</sup> and fluconazole,<sup>105</sup> which inhibit ergosterol biosynthesis. The imidazoles vary in their activity against different *Leishmania* species. They have most often been used for the treatment of cutaneous leishmaniasis, but failures occur. Pentamidine isethionate is an alternative for the treatment of visceral and cutaneous leishmaniasis, but it is associated with serious side effects. Preliminary data indicate that paromomycin administered intravenously has activity against pentavalent antimony-resistant *L. donovani*. Paromomycin has also been used topically with methylbenzethonium chloride in soft white paraffin for the treatment of cutaneous leishmaniasis caused by *L. major* and some other *Leishmania* species.<sup>106</sup> A number of other drugs and approaches have been studied, but the data are insufficient to recommend their general use.

## TREATMENT OF ECTOPARASITIC DISEASES

The major ectoparasites of humans, lice and scabies, are treated with malathion, permethrin, or alternative drugs (Table 13-9; Box 13-6).

**Table 13-9 Treatment of Ectoparasites**

Infection	Drug	Adult Dosage	Pediatric Dosage
Lice infestation ( <i>Pediculus humanus</i> , <i>P. capitis</i> , <i>Phthirus pubis</i> ) <sup>a</sup>			
Drug of choice:	0.5% Malathion <sup>b</sup> or 1% Permethrin <sup>c</sup>	Topically Topically	Topically Topically
Alternative:	Pyrethrins with piperonyl butoxide <sup>c</sup> or Ivermectin <sup>d,e</sup>	Topically 200 µg/kg × 3, days 1, 2, and 10	Topically 200 µg/kg × 3 days 1, 2, and 10
Scabies ( <i>Sarcoptes scabiei</i> )			
Drug of choice:	5% Permethrin	Topically <sup>f</sup>	Topically <sup>f</sup>
Alternatives: <sup>g</sup>	Ivermectin <sup>d,h</sup> or 10% Crotamiton	200 µg/kg once <sup>f</sup> Topically once/daily × 2 days	200 µg/kg once <sup>f</sup> Topically once/daily × 2 days

<sup>a</sup>For infestation of eyelashes with *P. pubis* lice, use petrolatum; TMP/SMX has also been used (Meinking TL; Curr Probl Dermatol 24:157, 1996). For pubic lice, treat with 5% permethrin or ivermectin as for scabies. TMP/SMX has also been effective together with permethrin for head lice. (Hipolito RB, et al: Pediatrics 107:E30, 2001).

<sup>b</sup>Yoon KS, et al: Arch Dermatol 139:994, 2003.

<sup>c</sup>A second application is recommended 1 week later to kill hatching progeny. Some lice are resistant to pyrethrins and permethrin (Meinking TL, et al: Arch Dermatol 138:220, 2002).

<sup>d</sup>An approved drug but considered investigational for this condition by the FDA.

<sup>e</sup>Ivermectin is effective against adult lice but has no effect on nits (Jones KN, English JC III: Clin Infect Dis 36:1355, 2003).

<sup>f</sup>In some cases, treatment may need to be repeated in 10–14 days.

<sup>g</sup>Lindane (gamma-benzene hexachloride; Kwell) should be reserved as a second-line agent. The FDA has recommended it should not be used for immunocompromised patients, young children, the elderly, and patients <50 kg.

<sup>h</sup>Ivermectin, either alone or in combination with a topical scabicide, is the drug of choice for crusted scabies in immunocompromised patients (del Giudice P: Curr Opin Infect Dis 15:123, 2004). The safety of oral ivermectin in pregnancy and young children has not been established.

### Box 13-6 Adverse Effects of Drugs Used in the Treatment of Ectoparasites

Crotamiton (Eurax [Westwood-Squibb])

**Occasional:** rash, conjunctivitis

Malathion (Ovide [Medicis])

**Occasional:** local irritation

Permethrin (Nix [GlaxoSmithKline], Elimite [Allergan]),

Pyrethrins and piperonyl butoxide (RID [Pfizer], others)

**Occasional:** allergic reactions

RICHARD D. PEARSON

### INTRODUCTION

This chapter provides an overview of major antibacterial, antimycobacterial, antifungal, and antiviral agents but does not include comprehensive information about the pharmacology, indications, dosing, or toxicities of all the chemotherapeutic agents used in the treatment of tropical infectious diseases. The treatment of specific infections is more thoroughly addressed in Section II, Pathogens. Additionally, drugs used against opportunistic infections and potentially serious drug interactions in human immunodeficiency syndrome (HIV)-infected patients are summarized. More complete discussions are found in pharmacology textbooks, and substantial additional information about indications, dosing, and toxicities may be found in *Medical Letters on Drugs and Therapeutics*.

### ANTIBACTERIAL DRUGS

Antibiotics, their pharmacology and indications, form the topic of entire textbooks. The increasingly worrisome emergence of resistance among bacteria has nearly outstripped even the impressive burgeoning of new antibiotics, and effective therapy often requires isolation of the pathogen and sensitivity testing to specific antimicrobial agents. Furthermore, infections in immunocompromised hosts or in “privileged sites,” such as cerebrospinal fluid (CSF) or endocarditic vegetations, often require bactericidal agents or synergistic antibiotic combinations. Treatment of common infections such as pneumonia, meningitis, and sepsis is fraught with increasing difficulty because of resistant organisms. For example, *Streptococcus pneumoniae* is increasingly resistant to penicillin and sometimes to cephalosporins and macrolides. *Listeria monocytogenes*, an important cause of meningitis, is resistant to even third-generation cephalosporins. Ampicillin is recommended for its treatment. Macrolides are indicated for “atypical” pneumonia caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or *Legionella pneumoniae*. In addition to gram-negative bacilli, staphylococci, particularly methicillin-resistant *Staphylococcus aureus* and *Candida*, have emerged as important causes of nosocomial infection. Adverse effects of antibiotics are also common, ranging from hypersensitivity reactions, including rash, fever, and anaphylaxis, most often seen with sulfonamides and  $\beta$ -lactam antibiotics, to nephrotoxicity, especially with aminoglycosides. Antibiotic-associated colitis or superinfections can occur with most antibiotics but are especially common with those whose broad spectrum alters the normal oropharyngeal, bowel, and other flora. This section focuses on selective principles of antibiotic therapy within the major classes of antibacterial drugs and lists the infections for which these agents are generally the drug of choice or a primary alternative. These are summarized in Table 14-1.

Shown in Figure 14-1 are the various mechanisms by which antibacterial agents exert either bactericidal or bacteriostatic activity against different microorganisms. The major

MRSA, methicillin-resistant *S. aureus*; LGV, lymphogranuloma venereum; VRE, vancomycin-resistant enterococci.

\*Confirm sensitivity as resistance is increasing (e.g., *Streptococcus pneumoniae* requiring cefotaxime, ceftriaxone, or, for high-level resistance, vancomycin plus rifampin or levofloxacin, gatifloxacin, or moxifloxacin).

†FDA-approved for complicated skin and skin structure infections.

\*Clarithromycin is not recommended for use in pregnancy or in patients receiving terfenadine therapy who have pre-existing cardiac abnormalities.

§Tetracyclines are generally not recommended for pregnant women or for children less than 8 years of age.

|| Aminoglycosides are useful only in combination therapy.

¶Fluoroquinolones are generally not recommended for children or pregnant women.

See Choice of antibacterial agents. Treatment Guidelines from The Medical Letter 2:13–24, 2004, for doses, toxicities, and alternatives.

**FIGURE 14-1** Antimicrobial sites of bactericidal or bacteriostatic action on microorganisms. The five general mechanisms are (1) inhibition of synthesis of the cell wall, (2) damage to the outer membrane, (3) modification of nucleic acid and DNA synthesis, (4) modification of protein synthesis (at ribosomes), and (5) modification of energy metabolism within the cytoplasm (at folate cycle). DHF, dihydrofolate; PABA, para-aminobenzoic acid; THF, tetrahydrofolate. (Adapted from Brody TE, Larner J, Minneman K, et al: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby-Year Book, 1998.)

bacterial cell wall inhibitors are  $\beta$ -lactam agents (such as penicillins, cephalosporins, and carbapenems) and vancomycin. Penicillins differ in their absorption, protein-binding characteristics, metabolism, and renal excretion, but in general all are well distributed throughout the body. In the presence of inflammation, CSF concentrations rise to around 5% of those in plasma. Adjustments in dosages of penicillin are generally not necessary until renal clearance decreases below 30 mL per minute. Penicillin G and penicillin V are active against most non- $\beta$ -lactamase-producing gram-positive and gram-negative cocci. Ampicillin and amoxicillin exhibit broader gram-negative coverage than penicillin does, but increasing resistance among *Haemophilus influenzae*, *Shigella*, and *Salmonella* has been seen in recent years. Penicillinase-resistant penicillins (e.g., methicillin, nafcillin, dicloxacillin) inhibit staphylococci and streptococci. The carboxypenicillins (carbenicillin and ticarcillin) have extended activity against *Pseudomonas aeruginosa* and other gram-negative bacilli. Because they are readily destroyed by  $\beta$ -lactamases, these agents are useful primarily when combined with a  $\beta$ -lactamase inhibitor. Ureidopenicillins (e.g., piperacillin, mezlocillin, and azlocillin) also exhibit extended activity against gram-negative organisms (including *Pseudomonas*), while retaining activity against streptococci. The combination of piperacillin with the  $\beta$ -lactamase inhibitor tazobactam renders this ureidopenicillin more effective against  $\beta$ -lactamase producing bacteria.

Cephalosporins are classified into generations based on their spectrum of antimicrobial activity. In general, first-generation cephalosporins have good activity against gram-positive organisms and moderate activity against gram-negative bacilli such as *Escherichia coli*. Some second-generation cephalosporins, such as cefotaxime, have enhanced activity against *Haemophilus* and gram-negative bacilli, but less activity than first-generation cephalosporins against staphylococci. Third-generation cephalosporins, in general, have less activity against staphylococci and more activity against streptococci, Enterobacteriaceae, *Neisseria*, and *Haemophilus* spp. Notably, ceftazidime and cefoperazone have less activity against streptococci but improved activity against *P. aeruginosa*. Third-generation cephalosporins, like penicillins, are widely distributed into body compartments. Cefotaxime and ceftriaxone enter the CSF and are widely used to treat meningitis. Ceftizoxime (and cefepime) also can be used to treat meningitis. Most cephalosporins are eliminated by renal mechanisms. Cefoperazone and ceftriaxone are primarily excreted by the biliary route. A relatively new category, fourth-generation cephalosporins, includes cefepime, which is approved for use in the United States. Fourth-generation cephalosporins have activity against both gram-positive cocci (comparable to that of cefotaxime or ceftriaxone) and excellent activity against *P. aeruginosa* (comparable to that of ceftazidime).

Penicillins are generally well tolerated. The most important life-threatening side effect is a type I hypersensitivity reaction, which occurs in up to 0.05% of treatment courses. A morbilliform skin eruption occurs in 3% to 5% of patients. Occasionally, penicillin can cause seizures when given in high doses, particularly in patients with concomitant renal failure. The incidence of anaphylaxis with cephalosporins is even less than that seen with penicillins. It is estimated that fewer than 5% of those who have anaphylactic reactions to penicillin are at risk for such a reaction with a cephalosporin.

The carbapenems—imipenem, meropenem, and ertapenem—all administered intravenously, are  $\beta$ -lactam antibiotics that are relatively resistant to  $\beta$ -lactamases. Because imipenem is hydrolyzed by a renal dihydropeptidase, it is combined with a renal dehydropeptidase inhibitor, cilastatin. Imipenem and meropenem reach therapeutic concentrations in CSF in patients with meningitis; however, imipenem may cause seizures in patients with underlying brain injury or impaired renal clearance. Clinical experience suggests that carefully adjusting imipenem dosing according to renal function or the use of meropenem may help decrease the risk of seizures. Imipenem and meropenem have excellent activity against gram-positive and gram-negative aerobes and anaerobes. Unlike imipenem and meropenem, ertapenem has minimal activity against *P. aeruginosa* or *Acinetobacter*. It offers the advantage of once daily dosing for infections caused by susceptible organisms.

Vancomycin, a glycopeptide cell wall inhibitor unrelated to  $\beta$ -lactams, is not absorbed orally and is primarily used intravenously. It is eliminated by glomerular filtration and is not removed by hemodialysis or peritoneal dialysis. Dosage should be adjusted in patients with impaired creatinine clearance. Vancomycin is useful for gram-positive (but not for gram-negative) bacteria, particularly methicillin-resistant *S. aureus* and methicillin-resistant coagulase-negative staphylococci. Oral vancomycin effectively treats *Clostridium difficile*-associated diarrhea; however, metronidazole is equally effective, less expensive, and perhaps less likely to foster the emergence of vancomycin-resistant enterococci. Vancomycin occasionally causes “red-man syndrome,” a histamine-mediated phenomenon characterized by erythema, especially around the head and neck, sometimes with hypotension. Vancomycin also can be ototoxic, particularly at higher plasma concentrations or when given in combination with aminoglycosides.

Some new agents with activity targeting gram-positive bacteria have become available in recent years. Daptomycin, a cyclic lipopeptide that binds to and depolarizes bacterial plasma membranes, resulting in cell death, was recently approved by the U.S. Food and Drug Administration (FDA) for the treatment of complicated skin and skin structure infections and appears to be similar in efficacy to vancomycin for this indication. It offers the advantage of once daily dosing and is a reasonable alternative to vancomycin. Linezolid, an oxazolidinone that inhibits protein synthesis at the bacterial ribosome has clinically useful activity against both *Enterococcus faecium* and *faecalis*, including many vancomycin-resistant enterococci and methicillin-resistant staphylococci. It has the advantage of being dosed orally, but its long-term use has been limited primarily by concerns for treatment-associated thrombocytopenia. Quinupristin/dalfopristin, a combination of streptogramins, also inhibits bacterial protein synthesis. It is active against methicillin-resistant *S. aureus* and *E. faecium*, including vancomycin-resistant strains, but not against *E. faecalis*. Disadvantages of quinupristin/dalfopristin include the requirement for infusion via a central venous catheter and frequent dose-limiting myalgias.

The macrolide antibiotics include erythromycin, clarithromycin, azithromycin, and dirithromycin. Erythromycin has broad gram-positive activity (including *S. pneumoniae*, *Streptococcus pyogenes*, and *Corynebacterium diphtheriae*) and inhibits *Bordetella pertussis*, legionellae, mycoplasmas, and chlamydiae. Erythromycin is distributed throughout the

body but does not achieve adequate concentrations to treat meningitis. The most common adverse effects of erythromycin are gastrointestinal. Transient hearing loss can be seen, especially at high doses. Clarithromycin is associated with fewer gastrointestinal side effects. Its spectrum of activity includes that of erythromycin plus activity against atypical mycobacteria and some *H. influenzae* spp. It is two to four times more active than erythromycin against staphylococci and streptococci. Azithromycin is better absorbed and better tolerated than erythromycin; it has an extremely long half-life and can be given once daily for 5 days. It is two to four times less active than erythromycin against staphylococci and streptococci but it is more active against *H. influenzae*. A single 1-g dose is effective for genital chlamydial infections. Erythromycin and clarithromycin should never be coadministered with terfenadine or astemizole because of potential cardiac toxicity (such as torsades de pointes). Recently approved by the FDA, telithromycin is the first of a new class of antibiotics, ketolides, which are structurally similar to macrolides but demonstrate enhanced activity against multidrug-resistant *S. pneumoniae*. Telithromycin is approved for acute bacterial exacerbation of chronic bronchitis, acute bacterial sinusitis, and mild to moderately severe community-acquired pneumonia.

Aminoglycosides are not absorbed orally but are given primarily by either intravenous or intramuscular injection. The antimicrobial spectrum of activity of aminoglycosides is limited to aerobic and facultative gram-negative bacilli. Nephrotoxicity occurs in 5% to 25% of patients and ototoxicity (vestibular or auditory) in 0.5% to 3.0% of patients. Renal toxicity is usually reversible, whereas ototoxicity often is not. Toxicity can typically be avoided by careful monitoring of blood levels and serial measurements of serum creatinine.

Tetracyclines are broad-spectrum agents that may be administered either orally or intravenously. They are typically well absorbed (best absorbed in the fasting state because tetracyclines chelate with divalent metals), widely distributed in body fluids, and renally excreted. Tetracyclines are the drug of choice for Rocky Mountain spotted fever, ehrlichiosis, and chlamydial infections; *Borrelia burgdorferi*, mycoplasmas, *Vibrio cholerae*, *Brucella* spp., and *Pseudomonas pseudomallei* are usually susceptible. Increasing resistance renders them less useful against many other bacterial strains. Tetracyclines may cause discoloration of teeth and bones in children less than 8 years of age and may cause photosensitivity in any patient.

Chloramphenicol (another inhibitor of bacterial ribosomal activity) is active against a broad range of aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, rickettsiae, and *Mycoplasma* spp. It is well absorbed from the gastrointestinal tract and can be given intravenously. Chloramphenicol is widely distributed throughout the body and, because of its lipid solubility, achieves high concentrations in brain tissue and CSF. The dose should be reduced in patients with hyperbilirubinemia. Chloramphenicol may cause reversible bone marrow suppression in adults receiving 4 g or more per day and causes aplastic anemia in 1 in 24,000 to 40,000 recipients. It has also been associated with optic neuritis and with gray baby syndrome in premature infants.

Clindamycin is well absorbed orally and can be given by intramuscular or intravenous dosing as well. Clindamycin penetrates most body compartments except brain tissue and CSF. Concentrations are inadequate to treat meningitis or

other brain infections except toxoplasmosis. The half-life of clindamycin is prolonged in severe liver disease. It is active against most gram-positive cocci (except enterococci) and many anaerobes. Clindamycin causes diarrhea in up to 20% of patients and pseudomembranous colitis in 3% to 5% of patients. It is rarely associated with hepatotoxicity and allergic reactions such as rash.

The quinolones constitute another class of antibacterials, DNA gyrase inhibitors, which inhibit DNA synthesis in bacterial but not mammalian cells. They are well absorbed orally and distributed widely. Absorption of several quinolones is impaired in the presence of magnesium, aluminum, calcium, zinc, and iron. Because the newer fluoroquinolones such as levofloxacin, gatifloxacin, and moxifloxacin have good activity against increasingly penicillin-resistant pneumococci, they are often considered for treatment of community-acquired pneumonia. Quinolones are effective against most Enterobacteriaceae, *Haemophilus* spp., gram-negative cocci, legionellae, mycoplasmas, and chlamydiae. Moxifloxacin also has activity against anaerobes. These agents are not the therapy of choice for infections with staphylococci and penicillin-susceptible streptococci. Although generally well tolerated, all quinolones can cause gastrointestinal upset and central nervous system (CNS) side effects, the latter occurring more commonly in the elderly. Because quinolones cause arthropathy in immature animals, they are not recommended for use in children or pregnant women. Quinolones decrease the clearance of theophylline.

Folic acid synthesis is inhibited by both trimethoprim and sulfonamides. The combination trimethoprim-sulfamethoxazole provides a potent sequential inhibition of folic acid synthesis and is useful in treating *S. aureus*, *S. pyogenes*, *S. pneumoniae*, *E. coli*, *Proteus mirabilis*, *Shigella* spp., *Salmonella* spp., *Pseudomonas cepacia*, *Pseudomonas pseudomallei*, *Yersinia enterocolitica*, and *Neisseria gonorrhoeae*. It is also useful in treating several protozoal infections, including *Pneumocystis carinii*, *Isospora belli*, and *Cyclospora cayetanensis*. Hypersensitivity reactions, Stevens-Johnson syndrome, and hematologic toxicities are some of the more common or serious complications of therapy with sulfamethoxazole.

## ANTIMYCOBACTERIAL DRUGS

The agents used for mycobacterial infections and their toxicities are summarized in Table 14-2. Susceptible strains of *Mycobacterium tuberculosis* are treated with isoniazid and rifampin with or without pyrazinamide, for 6 to 9 months. Where significant resistance (i.e., >4% to isoniazid) is possible, a four-drug regimen with isoniazid, rifampin, pyrazinamide, and either ethambutol or streptomycin is used until the sensitivities are known. In cases of multiple drug resistance, additional agents are required to achieve a minimum of three or more drugs to which the organism is susceptible. In addition, clarithromycin or azithromycin, ethambutol, and rifabutin are used in treatment of *Mycobacterium avium-intracellulare* complex infections in persons with acquired immunodeficiency syndrome (AIDS).

## ANTIFUNGAL DRUGS

The therapeutic armamentarium against fungi is expanding (Table 14-3). For many years, amphotericin B was the only

Table 14-2 Antimycobacterial Drugs

Drugs	Main Adverse Effects
Primary Agents Against <i>Mycobacterium tuberculosis</i> *	
Isoniazid (PO or IM, 5 mg/kg/day; 10–20 mg/kg/day for children; max. 300 mg/day for adults and children)	Hepatic toxicity, peripheral neuropathy
Rifampin (PO or IV, 10–20 mg/kg/day to 600 mg/day)	Hepatic toxicity, flulike syndrome
Pyrazinamide (PO 15–30 mg/kg/day to 1.5–2.5 g/day)	Hepatic toxicity, arthralgias, hyperuricemia
Ethambutol (Myambutol PO, 15–25 mg/kg/day)	Optic neuritis
Streptomycin (IM 15 mg/kg/day; 20–30 mg/kg/day for children)	Vestibular toxicity, renal damage
Alternative Antimycobacterial Drugs	
Capreomycin (Capastar IM 15 mg/kg/day; 15–30 mg/kg/day for children; max. 1 g)	Auditory and vestibular toxicity, renal damage
Kanamycin (Kantrex et al IM or IV 15 mg/kg/day; 15–30 mg/kg/day for children; max. 1 g)	Auditory and renal toxicity
Amikacin (Amikin IM or IV 15 mg/kg/day; 15–30 mg/kg/day for children)	
Cycloserine (Seromycin et al PO 250–500 mg bid; 10–20 mg/kg/day; max. 1 g)	Psychiatric symptoms, seizures
Ethionamide (Trecator-SC PO 250–500 mg bid; 15–20 mg/kg/day; max. 1 g)	Gastrointestinal disturbances, hepatic toxicity
Ciprofloxacin (Cipro PO 250–750 mg bid for adults only)	
Ofloxacin (Floxin PO 600–800 mg/day for adults only)	
Para-aminosalicylic acid (PAS; Teebacin PO 4–6 g bid; 75 mg/kg bid for children; max. 12 g)	Gastrointestinal disturbances
Clofazimine (Lamprene PO 100–200 mg; 1 mg/kg in children)	Gastrointestinal disturbances; ichthyosis; pigmentation of cornea, retina, skin
Additional Agents Particularly Useful for MAC†	
Clarithromycin PO 500 mg bid	↑ Rifabutin and AZT levels
Azithromycin PO 500 mg qd (500 mg 3 × wk when used as a component of MAC treatment regimen)	
Clarithromycin 500 mg bid or azithromycin 1200 mg qwk or 300 mg qd (for MAC prophylaxis)	
Rifabutin PO 300–450 mg qd	

AZT, zidovudine; MAC, *Mycobacterium avium*–*intracellulare* complex.

\*See Drugs for tuberculosis. Med Lett Drugs Ther 37:67–70, 1995, and Med Lett Drugs Ther 37:87–94, 1995, for details regarding indications, doses, and toxicities.

†See Table 14-11 for additional details.

Table 14-3 Systemic Antifungal Drugs

Antifungal Agent	Diseases for Which This Is the Drug of Choice or a Primary Alternative	Antifungal Agent	Diseases for Which This Is the Drug of Choice or a Primary Alternative
Amphotericin* (0.5–1.5 mg/kg IV)	Aspergillosis Blastomycosis Candidiasis (deep) (± flucytosine) Coccidioidomycosis (± flucytosine) Cryptococcosis Histoplasmosis Mucormycosis Paracoccidioidomycosis Sporotrichosis (systemic)	Oral azoles† Fluconazole (100–200 mg/day PO)	Candidiasis* (oropharyngeal, esophageal, vaginal) Coccidioidomycosis (requires 400–800 mg/day PO) Cryptococcosis (200 mg/day PO, for suppression) Pseudallescheriasis (ketoconazole or miconazole) <i>Madurella mycetomatis</i> § Blastomycosis
		Ketoconazole (400–800 mg/day PO)	

Continued

Table 14-3 Systemic Antifungal Drugs—Cont'd

Antifungal Agent	Diseases for Which This Is the Drug of Choice or a Primary Alternative	Antifungal Agent	Diseases for Which This Is the Drug of Choice or a Primary Alternative
Itraconazole (200 mg qd or bid PO)	Blastomycosis Histoplasmosis Pseudallescheriasis Paracoccidioidomycosis Sporotrichosis (cutaneous, itraconazole or saturated solution of potassium iodide) Chromomycosis ( <i>Fonsecaea pedrosi</i> et al)	Voriconazole (6 mg/kg IV q12h × 1 day, then 4 mg/kg IV q12h, then 200 mg bid PO) Echinocandin Caspofungin (70 mg IV × 1 day, then 50 mg IV once/day)	Alternative for Candidiasis (oropharyngeal, esophageal) Coccidioidomycosis Histoplasmosis Paracoccidioidomycosis  Invasive aspergillosis Refractory infection with <i>Scedosporium apiospermum</i> or <i>Fusarium</i> spp.  Invasive aspergillosis Deep <i>Candida</i> infections

\*Amphotericin B is given IV over about a 2- to 4-hour interval once a day or in double doses every other day. The duration of therapy with the drug usually ranges from 4 to 12 weeks. To decrease the severity of the initial reaction to the drug, if the patient is not dangerously ill, some clinicians begin with a 1-mg test dose, followed in 2 to 4 hours, if no severe reaction occurs, by a full therapeutic dose. Pretreatment with acetaminophen (Tylenol and others), aspirin, or hydrocortisone 25 mg IV can decrease the severity of the reactions. Treatment with meperidine (Demerol and others) 25 mg IV can shorten the duration of fever and chills.

†The optimal duration of treatment with the oral azole drugs is unclear. Depending on the disease, these drugs are continued for weeks or months or, particularly in AIDS patients, indefinitely. With ketoconazole and itraconazole, AIDS patients may have lower serum concentrations.

‡For patients with oropharyngeal disease, clotrimazole troches five times daily or nystatin solution (100,000 units/mL) 5 mL qid may be effective and are relatively inexpensive. For patients with fluconazole-resistant esophageal disease, amphotericin B 0.3 mg/kg IV can be used. *Candida krusei* infections are usually resistant to fluconazole. *Candida glabrata* infections are often resistant. Bladder irrigation with 50 mg/L of amphotericin B in sterile water has been used to treat *Candida* cystitis.

§Actinomycetoma (with *Actinomyces madurae*, *Nocardia*, et al) requires streptomycin + sulfamethoxazole-trimethoprim or dapsone.

Modified from Systemic antifungal drugs. Med Lett Drugs Ther 38:12, 1996; see also Antifungal drugs. Treatment guidelines. Medical Letter 3:7–14, 2005.

drug available for the treatment of most systemic fungal infections. Its untoward effects and requirement for parenteral administration are problematic (Table 14-4). Lipid-associated and liposomal amphotericin preparations, which may be less toxic, have recently become available. In the United States, these agents are approved only for treatment of aspergillosis in patients who are refractory to, or intolerant of,

conventional amphotericin B therapy. The introduction of the azoles—ketoconazole, fluconazole, itraconazole, and voriconazole—which are less toxic than amphotericin B and can be administered orally, constituted major advances. The echinocandin caspofungin has excellent clinical activity against *Aspergillus* spp. and *Candida* spp. and a favorable safety profile.

Table 14-4 Toxicities of the Antifungal Drugs

Drug	Toxicity
Amphotericin B	Systemic: fever, chills, headache, hypotension, tachycardia Gastrointestinal: nausea and vomiting Nephrotoxicity (may be decreased by sodium loading): hypomagnesemia, hypokalemia, renal tubular acidosis Hematologic: anemia, thrombocytopenia, mild leukopenia
Flucytosine	Bone marrow depression (increased with renal impairment if dosage adjustments are not made)
Itraconazole	Gastrointestinal: nausea, abdominal pain Drug interactions: increases levels of terfenadine and cisapride, which can be fatal; rhabdomyolysis if used concurrently with cyclosporine, lovastatin, simvastatin; absorption dependent on gastric acidity, decreased by H <sub>2</sub> blockers and antacids; others
Ketoconazole	Gastrointestinal intolerance, mild hepatotoxicity Others: rash, itching, dizziness, gynecomastia Endocrine: gynecomastia, altered libido, decreased potency, menstrual irregularity
Fluconazole	Drug interactions: increases levels of terfenadine and cisapride, which can be fatal; others Allergic: rash, Stevens-Johnson syndrome (rare), anaphylaxis (rare) Others: serious hepatotoxicity (rare)
Voriconazole	Drug interactions: increases levels of terfenadine and cisapride, which can be fatal; others
Caspofungin	Similar to other azoles except that approximately 30% have transient visual disturbances following dosing Generally well tolerated; pruritus and headache are most common

## ANTIVIRAL DRUGS AND THE TREATMENT OF OPPORTUNISTIC INFECTIONS IN PATIENTS WITH AIDS

The major antiviral agents and their indications and major toxicities are shown in Tables 14-5 and 14-6. The treatment of HIV infection is changing rapidly, and favored regimens combine nucleosides and protease inhibitors (PIs) or non-nucleoside reverse transcriptase inhibitors (NNRTIs) (see Table 14-6). Potentially serious drug interactions can occur, especially when protease inhibitors, which can affect the cytochrome

P-450 enzyme system in the liver, are used concurrently with antimycobacterial, antifungal, or other agents. Drugs that induce or inhibit the cytochrome P-450 system and their effects on substrate drugs are noted in Table 14-7, and other important drug interactions and cumulative toxicities are summarized in Tables 14-8 through 14-10. The approaches to treatment of opportunistic infections in patients with HIV infection are summarized in Table 14-11. Updated treatment recommendations from the U.S. Department of Health and Human Services are frequently posted at <http://www.aidsinfo.nih.gov>.

**Table 14-5 Antiviral Drugs (Other Than Antiretroviral Agents)\***

Antiviral (with Representative Adult Dose)	Virus or Disease for Which This is a First-Line Drug	Toxicity
Acyclovir (Zovirax and others) (IV or PO to 800 mg 5 ×/day × 5–10 days)	HSV, VZV	Gastrointestinal disturbances, crystalline nephropathy, headache, rash
Valacyclovir (Valtrex) (prodrug of acyclovir) (up to PO 1 g tid)	HSV, VZV	Similar to acyclovir; prolonged high doses may cause TTP/HUS
Famciclovir (Famvir) (prodrug of penciclovir) (PO 500 mg bid/tid)	HSV, localized VZV	Headache, nausea, diarrhea
Amantadine (Symmetrel) or rimantadine (Flumadine) (PO 200 mg/day × 5 days)	Influenza A	CNS anxiety, insomnia, confusion (usually minor, less with rimantadine)
Ganciclovir (Cytovene) (IV 5 mg/kg 1–2 ×/day)	CMV retinitis, pneumonia, others	Neutropenia, thrombocytopenia
Foscarnet (Foscavir) (IV 40–60 mg/kg q8h)	For resistant CMV, HSV, VZV	Renal dysfunction, hypocalcemia
Cidofovir (Vistide) (IV 5 mg/kg q2wk)	CMV retinitis (chronic suppression)	Nephrotoxicity, neutropenia, metabolic acidosis, uveitis, ocular hypotony
Interferon-alfa (Roferon-A, Intron-A, Alferon N) (SC or IM 3–10 million units 3 ×/wk × 4–6 mo) or Pegylated interferon-alfa 2b (PEG-Intron) (1 µg/kg once/wk SC × 48 wk)	Chronic hepatitis B, C <sup>†</sup> , D	Flulike symptoms, marrow suppression, et al
Ribavirin (Virazole) (aerosol 12–18 hr/day × 3–7 days, or IV)	RSV, Lassa fever, Sabia virus, CCHF, some hantavirus infections	Teratogenic, embryotoxic, hemolytic anemia
Ribavirin (Rebetrol, Rebetron) (1000–1200 mg/d PO)	Hepatitis C <sup>†</sup>	
Trifluridine (Viroptic) (topical, 1 drop 1% q2h × 10 days)	Ocular and mucocutaneous HSV	—
Vidarabine (Vira-A)	(HSV, VZV before acyclovir)	
Lamivudine (EpiVir HBV) (100 mg PO 1 ×/day × 1–3 yr)	Hepatitis B	Generally well tolerated; rare headache, nausea, dizziness
Fomiverson (Vitravene) (330 µg intravitreally q2wk × 2, then 2 ×/mo)	CMV retinitis	Iritis, vitritis, increased intraocular pressure and vision changes
Valganciclovir (Valcyte) (prodrug of ganciclovir) (900 mg PO bid × 21 days followed by 900 mg once daily)	CMV retinitis, others	Similar to ganciclovir
Ganciclovir intraocular implant (Vitrasert) (4.5 mg intraocularly q5–8mo)	CMV retinitis	Late retinal detachment
Oseltamivir (Tamiflu) (75 mg PO bid × 5 days for treatment; 75 mg PO once daily for prevention)	Influenza A or B treatment (within 36 hr) and prevention	Nausea and vomiting
Zanamivir (Relenza) (10 mg bid × 5 days by inhaler)	Influenza A or B treatment (within 2 days)	Nasal and throat discomfort, bronchospasm
Pencyclovir (Denavir) (1% cream applied q2h while awake × 4 days)	Oral labial HSV	

HSV, herpes simplex virus; VZV, varicella-zoster virus; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic-uremic syndrome; CMV, cytomegalovirus; RSV, respiratory syncytial virus; CCHF, Crimean-Congo hemorrhagic fever; CNS, central nervous system.

\*See Drugs for non-HIV viral infections. Med Lett Drugs Ther 44(W1123A), 2002, for full information about dosing, indications, and toxicities.

<sup>†</sup>For Hepatitis C infections, interferon and ribavirin are coadministered.

Table 14-6 Antiretroviral Drugs (with Usual Doses and Main Adverse Effects)

Antiretroviral	Main Adverse Effects	Antiretroviral	Main Adverse Effects
<b>Reverse Transcriptase (RT) Inhibitors</b>		<b>Protease Inhibitors</b>	
<i>Nucleoside and Nucleotide Analogs</i>		Saquinavir (Invirase) PO 600 mg tid; Fortovase PO 1200 mg tid)	Diarrhea; nausea; abdominal pain; poor bioavailability, especially with Invirase. ↓ levels with rifampin, rifabutin; antihistamine toxicity
Zidovudine (AZT, Retrovir) PO 200 mg tid or 300 mg bid	Anemia, neutropenia, nausea and vomiting, hemolytic anemia, malaise, myopathy, confusion, hepatitis	Ritonavir (Norvir) PO 600 mg q12h	Diarrhea; nausea and vomiting; paresthesias; transaminitis; asthenia; levels reduced by rifampin, rifabutin, dexamethasone; other drug toxicities
Didanosine (dideoxyinosine, ddI, Videx) PO 125–200 mg bid; Videx EC, PO 400 mg qd	Neuropathy, pancreatitis, gastrointestinal upset, ↓ absorption with itraconazole, ketoconazole, and possibly dapsone	Indinavir (Crixivan) PO 800 mg q8h	Renal stones, hyperbilirubinemia, gastric hypoacidity (↓ ddI absorption), other drug toxicities
Zalcitabine (dideoxycytidine, ddC, Hivid) PO 0.75 mg tid	Neuropathy, rash, stomatitis, esophageal ulceration, pancreatitis, fever	Nelfinavir (Viracept) PO 750 mg tid with food or PO 1250 mg bid with food	Diarrhea, asthenia, nausea, abdominal pain, headache, rash
Stavudine (d4T, Zerit) PO 40 mg bid (30 mg bid if <60 kg)	Neuropathy, transaminitis, rarely pancreatitis, lipoatrophy	Atazanavir (Regataz) 400 mg once daily	Indirect hyperbilirubinemia, prolonged PR interval, hyperglycemia, fat maldistribution.
Lamivudine (3TC, Epivir) PO 150 mg bid or PO 300 mg qd	Gastrointestinal upset, rare pancreatitis		
Zidovudine + lamivudine (Combivir) 1 tablet PO bid	See above		
Tenofovir disoproxil Fumarate (Viread) 300 mg PO bid	Asthenia, headache, renal insufficiency		
Abacavir (Ziagen) 300 mg PO qd	Hypersensitivity reaction (can be fatal)		
Emtricitabine (FTC, Emtriva) 200 mg PO qd	Headache, nausea, skin hyperpigmentation		
Abacavir + lamivudine + Zidovudine (Trizivir) 1 tablet PO bid	See above		
Abacavir + lamivudine (Epzicom) 1 tablet qd	See above		
Tenofovir + emtricitabine (Truvada) 1 tablet qd	See above		
<i>Non-nucleoside RT Inhibitors</i>			
Efavirenz (Sustiva) 600 mg PO qd	Rash, vivid dreams, dizziness, insomnia, impaired concentration	Lopinavir/ritonavir (Kaletra) 400 mg lopinavir + 100 mg ritonavir PO bid, with food	Diarrhea, nausea, vomiting, asthenia, liver function test abnormalities, glucose abnormalities, hyperlipidemia, fat maldistribution
Nevirapine (Viramune) PO 200 mg bid	Rash	Fosamprenavir (Lexiva) 1400 mg PO bid	Diarrhea, nausea, vomiting, fat maldistribution, skin rash, hyperglycemia, lipid abnormalities
Delavirdine (Rescriptor) PO 400 mg tid	Rash	<i>Fusion Inhibitors</i> Enfuvirtide (T-20, Fuzeon)	Local injection site reactions, increased rate of bacteria pneumonia, hypersensitivity reaction

\*Certain listed drugs are contraindicated based on theoretical considerations. Thus, drugs with narrow therapeutic indices and suspected metabolic involvement with cytochrome P-450-3A, -2D6, or unknown pathways are included in this table. Actual interactions may or may not occur among patients.

<sup>†</sup>HIV patients being treated with rifapentine have a higher rate of TB relapse than those treated with other rifamycin-based regimens; an alternative agent is recommended for this population.

<sup>‡</sup>Astemizole and terfenadine are not marketed in the United States.

<sup>§§</sup>The manufacturer of cisapride has a limited-access protocol in place for patients meeting specific clinical eligibility criteria.

<sup>¶¶</sup>Midazolam can be used with caution as a single dose and given in a monitored situation for procedural sedation.

<sup>¶¶</sup>This is likely a class effect.

<sup>¶¶</sup>Each 150-mg amprenavir Agenerase capsule has 109 IU (International Units) of vitamin E, and 1 mL of amprenavir oral solution has 46 IU of vitamin E. At FDA-approved doses, the daily amount of vitamin E in Agenerase is 58-fold increase over the federal government reference daily intake for adults. Patients should be cautioned to avoid supplemental doses of vitamin E. Multivitamin products containing minimal amounts of vitamin E are likely acceptable.

<sup>\*\*</sup>In one small study, higher doses of RTV or LPV/RTV offset rifampin-inducing activity of LPV. Of note, 28% of subjects discontinued due to increases in LFTs. The safety of this combination is still under evaluation.

#### Suggested Alternatives

*Crivastatin (no longer marketed in the United States), simvastatin, lovastatin:* pravastatin and fluvastatin have the least potential for drug-drug interactions; atorvastatin should be used with caution, using the lowest possible starting dose and monitoring closely; no pharmacokinetic data or safety data are available for coadministration of rosuvastatin with the antiretroviral agents.

*Rifabutin:* clarithromycin, azithromycin (MAI prophylaxis); clarithromycin, azithromycin, ethambutol (MAI treatment)

*Astemizole, terfenadine (no longer marketed in the United States):* desloratadine, loratadine, fexofenadine, cetirizine

*Midazolam, triazolam:* temazepam, lorazepam

From U.S. Department of Health and Human Services: Guidelines for the Use of Antiretroviral Agents in HIV-1 Infected Adults and Adolescents. Available at [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov).

**Table 14-8 Drug Interactions Between Antiretrovirals and Other Drugs: PIs, NNRTIs, and NRTIs**

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use		
	Indinavir (IDV)	Ritonavir* (RTV)	Saquinavir* (SQV)
<b>Antifungals</b>			
Ketoconazole	Levels: IDV ↑ 68% Dose: IDV 600 mg tid	Levels: ketoconazole ↑ 3 × Dose: use with caution; do not exceed 200 mg ketoconazole daily	Levels: SQV ↑ 3 × Dose: if ketoconazole dose is >200 mg/d, monitor for excessive diarrhea, nausea, abdominal discomfort, and adjust doses accordingly No data, but potential for bidirectional inhibition between voriconazole and PIs; monitor for toxicities
Voriconazole	Levels: no significant changes in AUC of azole or IDV (healthy subjects) Dose: standard	No data, but potential for bidirectional inhibition between voriconazole and PIs; monitor for toxicities	
<b>Antimycobacterials</b>			
Rifampin	Levels: IDV (unboosted) ↓ 89%; IDV (boosted) ↓ 87% Contraindicated	Levels: RTV ↓ 35% Dose: no change Increased liver toxicity possible Coadministration may lead to loss of virologic response if RTV sole PI Alternative antimycobacterial agents, such as rifabutin, should be considered Levels: rifabutin ↑ 4 × Dose: ↓ rifabutin to 150 mg qd or 3 ×/week† RTV: Maintain current dose if sole PI or part of a boosted regimen	Levels: SQV ↓ 84% Contraindicated unless using RTV+SQV Dose: SQV/RTV 400/400 mg bid, rifampin 600 mg qd or 3 ×/week  Levels: SQV ↓ 40% Contraindicated unless using SQV/RTV Dose: rifabutin 150 mg qd or 3 ×/week†
Rifabutin	Levels: IDV ↓ 32%; rifabutin ↑ 2 × Dose: ↓ rifabutin to 150 mg qd or 300 mg 3 ×/wk. IDV 1000 mg tid If RTV boosted, use rifabutin dosing recommendations for coadministration with RTV; continue current dose of boosted IDV		
Clarithromycin	Levels: Clarithromycin ↑ 53% No dose adjustment	Levels: Clarithromycin ↑ 77% Dose: adjust clarithromycin dose for moderate and severe renal impairment Levels: ethinyl estradiol ↓ 40% Use alternative or additional method	Levels: Clarithromycin ↑ 45% SQV ↑ 177% No dose adjustment No data
Oral contraceptives	Levels: norethindrone ↑ 26% Ethinylestradiol ↑ 24% No dose adjustment		
<b>Lipid-Lowering Agents</b>			
Simvastatin	Levels: potential for large increase in statin levels; avoid concomitant use	Levels: potential for large increase in statin levels; avoid concomitant use	Levels: potential for large increase in statin levels; avoid concomitant use
Lovastatin	Levels: potential for increase in AUC; use lowest possible starting dose of atorvastatin with careful monitoring	Levels: 450% ↑ when administered with SQV/RTV combination Use lowest possible starting dose of atorvastatin with careful monitoring	Levels: 450% ↑ when administered with SQV/RTV combination Use lowest possible starting dose of atorvastatin with careful monitoring
Atorvastatin			
Pravastatin	No data	Levels: 50% ↓ when administered with SQV/RTV combination; no dose adjustment needed	Levels: 50% ↓ when administered with SQV/RTV combination No dose adjustment needed

Table 14-8 Drug Interactions Between Antiretrovirals and Other Drugs: PIs, NNRTIs, and NRTIs—Cont'd

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use		
	Indinavir (IDV)	Ritonavir* (RTV)	Saquinavir* (SQV)
<b>Anticonvulsants</b>			
Carbamazepine Phenobarbital Phenytoin	Carbamazepine markedly ↓ IDV AUC Consider alternative agent	Carbamazepine: ↑ serum levels when coadministered with RTV Use with caution Monitor anticonvulsant levels Methadone ↓ 37% Monitor and titrate dose if needed May require ↑ methadone dose	Unknown but may markedly ↓ SQV levels Monitor anticonvulsant levels  Methadone AUC ↓ 20%; when coadministered with SQV/RTV 400/400 mg BID Dose: no adjustment for this PI regimen, but monitor and titrate to methadone response if necessary
Methadone	No change in methadone levels		
<b>Erectile Dysfunction Agents</b>			
Sildenafil	Sildenafil AUC ↑ threefold; use cautiously Start with reduced dose of 25 mg every 48 hours, and monitor for adverse effects	Sildenafil AUC ↑ 11-fold Use cautiously Start with reduced dose of 25 mg every 48 hours, and monitor for adverse effects Vardenafil AUC ↑ 49-fold RTV AUC ↓ 20%	Sildenafil AUC ↑ twofold Use a 25-mg starting dose of sildenafil
Vardenafil	Vardenafil AUC ↑ 16-fold IDV (unboosted) AUC ↓ 30% Dose: consider sildenafil instead of vardenafil if IDV unboosted Do not exceed vardenafil 2.5 mg in 72 hours if administered with RTV	Dose: Vardenafil: start with a 2.5-mg dose, and do not exceed a single 2.5-mg dose in 72 hours RTV: maintain current dose Tadalafil AUC ↑ 124% Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours	No data but vardenafil AUC may be substantially increased Start with a 2.5-mg dose, and do not exceed a single 2.5-mg dose in 24 hours Do not exceed a single 2.5-mg dose in 72 hours if administered with RTV Concomitant administration will result in substantial increase in tadalafil AUC and half-life (normal = 17.5 hr)
Tadalafil	Concomitant administration will result in substantial increase in tadalafil AUC and half-life (normal = 17.5 hr) Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours Grapefruit juice ↓ IDV levels by 26% Vitamin C ≥ 1 g/d ↓ IDV AUC by 14% and Cmin by 32% Itraconazole: reduce IDV (unboosted) dose to 600 mg TID; do not exceed 200 mg itraconazole twice daily RTV boosted regimen: see RTV	Many possible interactions Desipramine ↑ 145%; reduce dose Trazadone AUC ↑ 60%; use lowest dose, and monitor for CNS and CV adverse effects Theophylline ↓ 47%; monitor theophylline levels	Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours Grapefruit juice ↑ SQV levels Dexamethasone ↓ SQV levels RTV boosted regimen: see RTV
Miscellaneous			

Drug Interactions Requiring Dose Modifications or Cautious Use			
Drugs Affected	Nelfinavir (NFV)	Amprenavir (APV)	Fosamprenavir (fos-APV)
<b>Antifungals</b>			
Ketoconazole	No dose adjustment necessary	Levels: APV ↑ 31% Ketoconazole ↑ 44% Dose: standard	Presumably similar interactions (an increase in both APV and ketoconazole levels) and recommendation as APV Consider ketoconazole dose reduction if dose is > 400 mg/d If fos-APV/r: use with caution; do not exceed 200 mg ketoconazole daily Presumably similar interaction and recommendation as APV
Voriconazole	No data, but potential for bidirectional inhibition between voriconazole and PIs exists; monitor for toxicities	No data, but potential for bidirectional inhibition between voriconazole and PIs exists; monitor for toxicities	
<b>Antimycobacterials</b>			
Rifampin <sup>s</sup>	Levels: NFV ↓ 82% Should not be coadministered	Levels: APV AUC ↓ 82% No change in rifampin AUC Should not be coadministered	Presumably similar interaction and recommendation as APV
Rifabutin	Levels: NFV ↓ 32% Rifabutin ↑ 2 × Dose: ↓ rifabutin to 150 mg qd or 300 mg 3 ×/week ↑ NFV dose to 1000 mg tid	Levels: APV AUC ↓ 15% rifabutin ↑ 193% Dose: No change in APV dose; decrease rifabutin to 150 mg qd or 300 mg 3 ×/week <sup>†</sup> If RTV boosted, use rifabutin dosing recommendations for coadministration with RTV; continue current dose of boosted APV	Similar interaction and recommendation as APV if fos-APV unboosted If RTV boosted fos-APV, dose reduce rifabutin to 150 mg QOD or 3 ×/wk <sup>†</sup>
Clarithromycin	No data	Levels: APV AUC ↑ 18% No change in clarithromycin AUC No dose adjustment	Presumably similar interaction and recommendation as APV
Oral contraceptives	Levels: norethindrone ↓ 18% ethinyl estradiol ↓ 47% Use alternative or additional method	Levels: ↑ ethinyl estradiol and norethindrone levels; APV levels ↓ 20% Do not coadminister; alternative methods of contraception are recommended	Presumably similar interaction as APV Do not coadminister; alternative methods of contraception are recommended
<b>Lipid-lowering Agents</b>			
Simvastatin	Avoid concomitant use Simvastatin AUC ↑ 505%—not recommended	Levels: potential for large increase in statin levels Avoid concomitant use	Presumably similar interaction and recommendation as APV
Lovastatin	Potential for large increase in Lovastatin AUC—not recommended		
Atorvastatin (ATO)	ATO AUC ↑ 74%—use lowest possible starting dose or atorvastatin with careful monitoring	ATO levels have potential for large increase Use lowest possible starting dose of atorvastatin with careful monitoring No data	ATO AUC ↑ 150% Maximum ATO dose of 20 mg/d; use with careful monitoring and consider alternative agent
Pravastatin	No data	No data	No data

Table 14-8 Drug Interactions Between Antiretrovirals and Other Drugs: PIs, NNRTIs, and NRTIs—Cont'd

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use		
	Nelfinavir (NFV)	Amprrenavir (APV)	Fosamprenavir (fos-APV)
<b>Anticonvulsants</b>			
Carbamazepine Phenobarbital Phenytoin	Unknown but may decrease NFV levels substantially Monitor anticonvulsant levels and virologic response Consider obtaining NFV levels NFV may decrease methadone levels but minimal effect on maintenance dose Monitor and titrate dose if needed May require ↑ methadone dose	Unknown, but may decrease APV levels substantially Monitor anticonvulsant levels and virologic response Consider obtaining APV levels Methadone levels ↓ 13% APV C <sub>min</sub> ↓ 25% Monitor and titrate methadone if needed	Presumably similar interaction and recommendation as APV  Presumably similar interaction and recommendation as APV
<b>Erectile Dysfunction Agents</b>			
Sildenafil	Sildenafil AUC ↑ 2–11-fold; use cautiously Start with reduced dose of 25 mg every 48 hours, and monitor for adverse effects	Sildenafil AUC ↑ 2–11-fold; use cautiously Start with reduced dose of 25 mg every 48 hours, and monitor for adverse effects	Similar interaction and recommendations as APV
Vardenafil	No data but vardenafil AUC may be substantially increased Start with a 2.5-mg dose, and do not exceed a single 2.5-mg dose in 24 hours Do not exceed 2.5 mg in 72 hours if administered with RTV	No data, but vardenafil AUC may be substantially increased Start with a 2.5-mg dose, and do not exceed a single 2.5 mg dose in 24 hours Do not exceed 2.5 mg in 72 hours if administered with RTV	Similar interaction and recommendations as APV
Tadalafil	Concomitant administration will result in substantial increase in tadalafil AUC and half-life (normal = 17.5 hr) Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours	Tadalafil half-life = 17.5 hours Concomitant administration will result in substantial increase in tadalafil AUC and half-life (normal = 17.5) Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours	Similar interaction and recommendations as APV

Drug Interactions Requiring Dose Modifications or Cautious Use		
Drugs Affected	Atazanavir (ATV)	Lopinavir (LPV)
<b>Antifungals</b>		
Ketoconazole	No dosage adjustment necessary	Levels: LPV AUC ↓ 13%; ketoconazole ↑ threefold Dose: use with caution; do not exceed 200 mg ketoconazole daily
Voriconazole	No data, but potential for bidirectional inhibition between voriconazole and PIs exists; monitor for toxicities	No data, but potential for bidirectional inhibition between voriconazole and PIs exists; monitor for toxicities
<b>Antimycobacterials</b>		
Rifampin <sup>s</sup>	Should not be coadministered	Levels: LPV AUC ↓ 75%; should not be coadministered A safe and effective dose of LPV/r that can be given with rifampin has not been established <sup>s</sup>
Rifabutin	Levels: rifabutin AUC ↑ 2.5-fold Dose: ↓ rifabutin dose to 150 mg qod or 3 ×/wk <sup>t</sup> ATV dose standard	Levels: rifabutin AUC ↑ threefold; 25-O-desacetyl metabolite ↑ 47.5-fold Dose: decrease rifabutin dose to 150 mg qod or 3 ×/week; LPV/r: standard
Clarithromycin	Levels: clarithromycin AUC ↑ 94% and may cause QTc prolongation Clarithromycin active metabolic concentrations are significantly reduced Dose: ↓ clarithromycin dose by 50%; consider alternative therapy	Levels: ↑ clarithromycin AUC 77% Dose: adjust clarithromycin dose for moderate and severe renal impairment
Oral contraceptives	Levels: ethinyl estradiol AUC ↑ 48%, norethindrone AUC ↑ 110% Dose: use lowest effective dose or alternative methods	Levels: ethinyl estradiol ↓ 42% Use alternative or additional method
<b>Lipid-lowering Agents</b>		
Simvastatin	Levels: potential for large increase in statin levels; avoid concomitant use	Levels: potential for large increase in statin levels Avoid concomitant use
Lovastatin	Atorvastatin levels have potential for large increase	Atorvastatin AUC ↑ 5.88-fold
Atorvastatin (ATO)	Use lowest possible starting dose of atorvastatin with careful monitoring	Use lowest possible starting dose of atorvastatin with careful monitoring
Pravastatin	No data	Paravastatin AUC ↑ 33%; no dosage adjustment necessary
<b>Anticonvulsants</b>		
Carbamazepine	Unknown but may decrease ATV levels substantially	Many possible interactions: carbamazepine: ↑ levels when coadministered with RTV
Phenobarbital	Monitor anticonvulsant levels	Use with caution; monitor anticonvulsant levels
Phenytoin		Phenytoin: ↓ levels of LPV, RTV, and ↓ levels of phenytoin when administered together; avoid concomitant use
Methadone	No data	Methadone AUC ↓ 53% Monitor and titrate dose if needed May require ↑ methadone dose

Continued

Table 14-8 Drug Interactions Between Antiretrovirals and Other Drugs: PIs, NNRTIs, and NRTIs—Cont'd

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use	
	Atazanavir (ATV)	Lopinavir (LPV)
<b>Erectile Dysfunction Agents</b>		
Sildenafil	Sildenafil levels have potential for increase Start with reduced dose of 25 mg every 48 hours, and monitor for adverse effects	Sildenafil AUC ↑ 11-fold in combination with RTV; use cautiously Start with reduced dose of 25 mg every 48 hours, and monitor for adverse effects
Vardenafil	No data, but vardenafil AUC may be substantially increased Start with a 2.5-mg dose, and do not exceed a single 2.5-mg dose in 24 hours	No data, but vardenafil AUC may be substantially increased Start with a 2.5-mg dose, and do not exceed a single 2.5-mg dose in 72 hours
Tadalafil	Do not exceed 2.5 mg in 72 hours if administered with RTV Concomitant administration will result in substantial increase in tadalafil AUC and half-life (normal = 17.5 hr); start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours	Tadalafil AUC ↑ 124% when coadministered with RTV Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours
Miscellaneous	Diltiazem AUC ↑ 125%, ↓ diltiazem dose by 50%; ECG monitoring is recommended Calcium channel blockers: caution is warranted; dose titration should be considered; ECG monitoring is recommended ATV inhibits UGT and may interfere with irinotecan metabolism; avoid concomitant use H <sub>2</sub> -receptor antagonists: reduced ATV concentrations are expected with simultaneous administration; separate dosing by 12 hours Antacids and buffered medications: reduced ATV concentrations are expected with simultaneous administration; give ATV 2 hr before or 1 hr after these medications RTV boosted regimen: see RTV	See Miscellaneous RTV recommendations, below

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use		
	Nevirapine (NVP)	Delavirdine (DLV)	Efavirenz (EFV)
<b>Antifungals</b>			
Ketoconazole	Levels: ketoconazole ↓ 63% NVP ↑ 15% to 30% Dose: not recommended	No data	No data
Voriconazole	No data, but potential for bidirectional interaction between voriconazole and NNRTIs exists; monitor for toxicities and voriconazole effectiveness	No data, but potential for bidirectional inhibition between voriconazole and delavirdine exists; monitor for toxicities	No data, but potential for bidirectional interaction between voriconazole and NNRTIs exists; monitor for toxicities and voriconazole effectiveness
<b>Antimycobacterials</b>			
Rifampin	Levels: NVP ↓ 20% to 58% Virologic consequences are uncertain; the potential for additive hepatotoxicity exists Use of this combination is not recommended; however, if used, coadministration should be done with careful monitoring Levels: NVP ↓ 16% No dose adjustment <sup>l</sup>	Levels: DLV ↓ 96% Contraindicated	Levels: EFV ↓ 25% Dose: consider ↑ EFV to 800 mg qd
Rifabutin		Levels: DLV ↓ 80% Rifabutin ↑ 100% Not recommended	Levels: EFV unchanged Rifabutin ↓ 35% Dose: ↑ rifabutin dose to 450–600 mg qd or 600 mg 3 ×/wk <sup>ll</sup> EFV: standard
Clarithromycin	Levels: NVP ↑ 26% Clarithromycin ↓ 30% Monitor for efficacy or use alternative agent	Levels: clarithromycin ↑ 100%, DLV ↑ 44% Dose-adjust for renal failure	Levels: clarithromycin ↓ 39% Monitor for efficacy, or use alternative agent
Oral contraceptives	Levels: ethinyl estradiol ↓ approx 20%; use alternative or additional methods	No data	Levels: ethinyl estradiol ↑ 37% No data on other component Use alternative or additional methods

*Continued*

Table 14-8 Drug Interactions Between Antiretrovirals and Other Drugs: PIs, NNRTIs, and NRTIs—Cont'd

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use		
	Nevirapine (NVP)	Delavirdine (DLV)	Efavirenz (EFV)
<b>Lipid-lowering Agents</b>			
Simvastatin	No data	Levels: potential for large increase in statin levels; avoid concomitant use	No data
Lovastatin			
Pravastatin	No data	No data	No data
<b>Anticonvulsants</b>			
Carbamazepine	Unknown	Unknown but may decrease DLV levels substantially	Use with caution
Phenobarbital	Use with caution	Monitor anticonvulsant levels	Monitor anticonvulsant levels
Phenytoin	Levels: NVP unchanged	No data	Levels: methadone ↓ significantly
Methadone	Methadone ↓ significantly		Titrate methadone dose to effect
	Titrate methadone dose to effect		
Miscellaneous	No data	May increase levels of dapson, warfarin, and quinidine	Monitor warfarin when used concomitantly
		Sildenafil: potential for increased concentrations and adverse effects; use cautiously	
		Start with reduced dose of 25 mg every 48 hours and monitor for adverse effects	
		Vardenafil: no data, but vardenafil AUC may be substantially increased	
		Start with a 2.5-mg dose, and do not exceed a single 2.5-mg dose in 24 hours	
		Tadalafil: no data, but concomitant administration will likely result in substantial increase in tadalafil AUC and half-life (normal = 17.5 hr)	
		Start with a 5-mg dose, and do not exceed a single dose of 10 mg every 72 hours	
		Atorvastatin levels have potential for large increase; use lowest possible starting dose of atorvastatin with careful monitoring	

Drug Interactions Requiring Dose Modifications or Cautious Use				
Drugs Affected	Zidovudine (ZDV)	Stavudine (d4T)	Didanosine (ddI)	Tenofovir (TDF)
Methadone	No data	Levels: d4T ↓ 27%; methadone unchanged No dose adjustment	Levels: EC ddI unchanged Buffered ddI AUC ↓ 63%; methadone unchanged Dose: no change in EC ddI. May consider buffered ddI dose to increase or maintain standard	No data
<b>Miscellaneous</b>				
Ribavirin	Ribavirin inhibits phosphorylation of ZDV; this combination should be avoided if possible, or closely monitor virologic response	No data	Coadministration not recommended; ribavirin increases the intracellular levels of the active metabolite of ddI and may cause serious toxicities	No data
Didanosine	No data	Peripheral neuropathy, lactic acidosis, and pancreatitis seen with this combination; use with caution and only if potential benefit outweighs potential risks	No data	Levels: ddI AUC ↑ by 44%; Cmax ↑ by 28% Monitor for ddI-associated toxicities For patients > 60 kg, 250 mg/day of ddI EC is recommended
Atazanavir (ATV)	No data	No data	Buffered ddI + ATV simultaneously: Levels: ↓ AUC of ATV 87%; take ATV (with food) 2 hr before or 1 hr after buffered ddI No interaction is expected with ddI-EC; however, dosing should be at different times, as ATV should be taken with food and ddI-EC on an empty stomach	ATV 400 + TDF 300 Levels: ATV AUC ↓ 25% and Cmin ↓ by 40%; TDF AUC ↑ by 24%; avoid concomitant use ATV + RTV 300/100 mg qd + TDF 300 mg qd Levels: ATV AUC ↓ by 25% and Cmin by 23%; ATV Cmin was higher with RTV than ATV without RTV Consider ATV + RTV (300/100 mg qd) for coadministration with TDF (300 mg qd); however, pharmacokinetic, safety, and virologic data are limited

Continued

Table 14-8 Drug Interactions Between Antiretrovirals and Other Drugs: PIs, NNRTIs, and NRTIs—Cont'd

Drugs Affected	Drug Interactions Requiring Dose Modifications or Cautious Use			
	Zidovudine (ZDV)	Stavudine (d4T)	Didanosine (ddI)	Tenofovir (TDF)
Indinavir (IDV)	No data	No data	Buffered ddI and IDV simultaneously: Levels: ↓ AUC of IDV; take IDV 1 hr before or after buffered ddI	No data
Lopinavir/ritonavir	No data	No data	No data	LPV/r 400/100 AUC ↓ 15%; TDF AUC ↑ 34%; clinical significance of interaction is unknown
Lamivudine plus (Abacavir or Didanosine)	No data	No data	No data	High rate of early virologic nonresponse with 3TC and ABC plus TDF; combination should be avoided
Cidofovir	No data	No data	ddl + oral ganciclovir (GCV): ddl AUC ↑ 111%; GCV AUC ↓ 21%; Appropriate doses for the combination of ddI and oral GCV have not been established	Possibly competes for active tubular secretion with tenofovir; may increase serum concentration of these drugs and/or tenofovir
Ganciclovir				
Valganciclovir				Monitor for dose-related toxicities

\*Drugs for which plasma concentrations may be decreased by coadministration with ritonavir: anticonvulsants (warfarin), anticonvulsants (phenytoin, divalproex, lamotrigine), antiparasitics (atovaquone).  
<sup>†</sup>Rifabutin 3 ×/wk is recommended if CD4 cell count is <100/mm<sup>3</sup>.

<sup>‡</sup>Some drug interaction studies were conducted with Invirase. May not necessarily apply to use with Fortovase.

<sup>§</sup>Limited data on RTV-SQV and LPV-RTV demonstrate that RTV compensates, to a degree, for rifampin induction. In one small study, higher doses of ritonavir (up to 400 mg per dose) or an increased dose of LPV/RTV 800/200 mg were needed to offset rifampin-inducing activity of LPV; the standard dose of rifampin was used in these studies. Of note, 28% of subjects discontinued due to increases in LFTs. The safety of this combination is not established. If coadministered, close monitoring is recommended, as is measuring LPV concentrations.

<sup>||</sup>These recommendations apply to regimens that do not include PIs, which can substantially increase rifabutin levels.

From U.S. Department of Health and Human Services: Guidelines for the Use of Antiretroviral Agents in HIV-1 Infected Adults and Adolescents. Available at [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov).

**Table 14-9 Drug Effects on Concentration of Protease Inhibitors (PIs)**

Drug Affected	Ritonavir	Saquinavir*	Nelfinavir	Amprenavir	Lopinavir/Ritonavir	Atazanavir
<b>Protease Inhibitors</b>						
Indinavir (IDV)	Levels: IDV ↑ 2–5 × Dose: 400/400 mg or 800/100 mg or 800/200 mg IDV/RTV bid Caution: renal events may be increased with higher IDV concentrations	Levels: IDV no effect SQV ↑ 4–7 × <sup>†</sup> Dose: insufficient data	Levels: IDV ↑ 50%; NFV ↑ 80% Dose: limited data for IDV 1200 mg bid + NFV 1250 mg bid	Levels APV AUC ↑ 33% Dose: not established	Levels: IDV AUC and Cmin ↑ Dose: IDV 600 mg bid	Coadministration of these agents is not recommended because of potential for additive hyperbilirubinemia
Ritonavir (RTV)	No data	Levels: RTV no effect SQV ↑ 20 × <sup>†</sup> Dose: 1000/100 mg SQV (sgc or hgc)/RTV bid or 400/400 mg bid	Levels: RTV no effect; NFV ↑ 1.5 × Dose: RTV 400 mg bid + NFV 500–750 mg bid	Levels: APV AUC ↑ 2.5–3.5-fold Dose: 600/100 mg APV/RTV bid, or 1200/200 mg APV/RTV qd	Lopinavir is co-formulated with ritonavir as Kaletra	ATV/r 300/100 ↑ ATV AUC by 238%
Saquinavir (SQV)	No data	No data	Levels: SQV ↑ 3–5 ×; NFV ↑ 20% <sup>†</sup> Dose: standard NFV; Fortovase 800 mg tid or 1200 mg bid	Levels: APV AUC ↓ 32% Dose: insufficient data	Levels: SQV <sup>†</sup> AUC and Cmin ↑ Dose: SQV 1000 mg bid, LPV/r standard	SQV 1200 mg qd + ATV 400 qd ↑ SQV AUC by 449%; no formal recommendation
Nelfinavir (NFV)	No data	No data	No data	Levels: APV AUC ↑ 1.5-fold Dose: insufficient data	Levels: LPV ↓ 27%; NFV ↑ 25% Dose: insufficient data	No data
Amprenavir (APV)	No data	No data	No data	No data	APV: AUC and Cmin increased relative to APV without RTV; APV AUC and Cmin reduced relative to APV + RTV; LPV Cmin may be decreased relative to LPV/r Dose: APV 600–750 mg bid; LPV/r standard, or consider dose increase to 533/133 mg bid Consider monitoring PI concentrations	No data
Fosamprenavir (fos-APV)	Fos-APV: AUC and Cmin ↑ 100% and 400%, respectively, with 200 mg RTV ARV-experienced should receive boosted regimen	Levels: APV AUC ↓ 32% Dose: insufficient data	No data	No data	Fos-APV: Cmin ↓ 64% (at dose of 700 mg bid with 100 mg bid of RTV) LPV: Cmin ↓ 53% (at LPV/r dose of 400/100) Should not be coadministered; doses are not established	No data
Lopinavir/Ritonavir (LPV/RTV)	No data	No data	No data	No data	No data	No information with LPV/ATV; RTV 100 mg ↑ ATV AUC by 238%

\*Several drug interaction studies have been completed with saquinavir given as Invirase or Fortovase. Results from studies conducted with Invirase may not be applicable to Fortovase.

<sup>†</sup>Study conducted with Fortovase.

\*Study conducted with Invirase.

**Table 14-11** Drugs Used Against Selected Opportunistic Infections

Infection/Drug	Usual Prophylactic or Suppressive Doses
Pneumocystis pneumonia (PCP)	
Trimethoprim (TMP)-sulfamethoxazole (SMX)/day PO or IV TMP 15 mg/kg/day × 3 wk	PO 1 double-strength (DS) tab qd or 3 ×/wk (e.g., 800 mg SMX + 160 mg TMP)
Pentamidine isethionate IV 3–4 mg/kg/day × 3 wk	300 mg inhaled monthly
Trimetrexate (+ folinic acid 20 mg/m <sup>2</sup> q6h × 3 wk) IV 45 mg/m <sup>2</sup> × 3 wk	—
Dapsone (+ trimethoprim 5 mg/kg tid PO × 3 wk) PO 100 mg/day × 3 wk	PO 100 mg 2 ×/wk or PO 100 mg/day + 50 mg pyrimethamine 2 ×/wk
Atovaquone PO 750 mg bid × 3 wk	—
Clindamycin (300 mg PO—600 mg IV qid × 3 wk) and primaquine (15 mg base PO qd × 3 wk)	—
Prednisone, in addition to TMP/SMX, if patient acutely ill, pO <sub>2</sub> <70 mm Hg (40 mg bid × 5 days, then 40 mg qd × 5 days, then 20 mg qd × 11 days)	—
Toxoplasmosis	
Pyrimethamine PO 50–100 mg qd and sulfadiazine PO 1.0–1.5 g q6h, or pyrimethamine + clindamycin	Pyrimethamine PO 25–50 mg qd and sulfadiazine 0.5–1.0 g q6h for suppression
Cryptosporidiosis	
Aminosalicylic acid (paromomycin) PO 500–750 mg qid	—
Nitazoxanide PO 0.5–1.0 g bid × 14 days	—
Mucosal candidiasis	
Nystatin PO 0.5–1.0 mU 3–5 ×/day or clotrimazole 10 mg 5 ×/day	—
Fluconazole PO 100–200 mg qd	—
Ketoconazole PO 200–400 mg qd	—
Cryptococcosis	
Amphotericin B 0.7–1.0 mg/kg/day + 5 FC 25 mg/kg PO qid, then fluconazole 400 mg PO × 8 wk	Fluconazole 200 mg PO qd for suppression
Herpes simplex virus (HSV) or varicella-zoster virus (VZV) infections	
Acyclovir 200–800 mg PO 5 ×/day or 10 mg/kg IV q8h × 1–2 wk for VZV	For suppression: 400 mg PO bid
Foscarnet 40 mg/kg IV q8h	40 mg/kg IV qd
Cytomegalovirus (CMV) infections	
Ganciclovir IV 5 mg/kg q12h	For suppression: IV 5–6 mg/kg qd or 5 ×/wk or PO 1 g tid po 1 g tid
Intraocular ganciclovir implant + valgancyclovir 900 mg PO bid with food × 14–21 days, then valgancyclovir 900 mg/day	
Foscarnet	
IV 60–90 mg/kg q8–12h	IV 90–120 mg/kg qd
Cidofovir (beware of nephrotoxicity)	
Mycobacterium-avium complex (MAC)	
Clarithromycin PO 500 mg bid	For primary prophylaxis:
or	Azithromycin 1200 mg/PO/week
+	or
Azithromycin PO (500 mg/day or some use 500 mg 3 ×/wk)	Clarithromycin 500 mg PO bid
+	
Ethambutol 15–25 mg/kg/day	
+	
Rifabutin 300 mg PO qd	
Syphilis	
Penicillin	
IM 2.4 million units benzathine weekly × 1–3 wk or doxycycline 100 mg PO bid × 2–4 wk or IV 12–24 million units/day × 2 wk or IM 2.4 million units procaine qd × 10 days with 500 mg probenecid PO bid (one of the latter 2 regimens needed for neurosyphilis)

## Surveillance for Emerging Infectious Diseases and Bioterrorism Threats

RAY R. ARTHUR  
JAMES W. LEDUC  
JAMES M. HUGHES

### INTRODUCTION

Despite advances in science, technology, and medicine that have improved disease prevention and management, endemic and emerging infectious diseases continue to pose threats to domestic and global health. Established diseases such as malaria, tuberculosis (TB), and human immunodeficiency virus (HIV) infection still proliferate, fueled in part by antimicrobial resistance.<sup>1,2</sup> The increasing speed and volume of international travel, migration, and trade create new opportunities for microbial spread, and the prospect of a deliberate release of pathogenic microbes underscores the importance of preparedness to address the unexpected.<sup>3</sup> The example of severe acute respiratory syndrome (SARS), a previously unknown disease that spread rapidly across countries and continents in 2003, illustrates the vulnerability of the global community to new microbial threats and highlights the need for increased vigilance and strengthened response capacity.<sup>4,5</sup>

The current state of readiness to address new disease agents is outlined in the 2003 Institute of Medicine report, *Microbial Threats to Health: Emergence, Detection, and Response*.<sup>6</sup> Building on the Institute's 1992 report,<sup>7</sup> which sought to dispel complacency about the risk of infectious diseases, the new report calls for raised awareness and aggressive global action to address the developments of the intervening decade. These developments include the continued evolution of antimicrobial resistance, the ongoing threat of an influenza pandemic, the increased transborder spread of contagious diseases, the upsurge in infections arising from animal reservoirs, and the threat of intentional biological attacks, as well as the availability of new technologies for diagnosing and preventing disease and for linking public health practitioners around the world.

Recent domestic challenges have included the introduction of West Nile encephalitis<sup>8,9</sup> and monkeypox<sup>10</sup> into the

United States, the anthrax episodes of fall 2001,<sup>11</sup> and multi-state outbreaks involving contaminated food products.<sup>12-14</sup> Internationally, public health officials have faced the emergence of Nipah virus<sup>15</sup> and SARS,<sup>4</sup> the intensified global spread of dengue,<sup>16,17</sup> Ebola outbreaks of unprecedented magnitude,<sup>18</sup> and the direct avian-to-human transmission of influenza.<sup>19,20</sup> Each of these examples illustrates the global implications of local problems, the role of strong health intelligence networks in addressing emerging infections, and the importance of data on the incidence of natural background diseases in recognizing unusual disease events.<sup>21</sup>

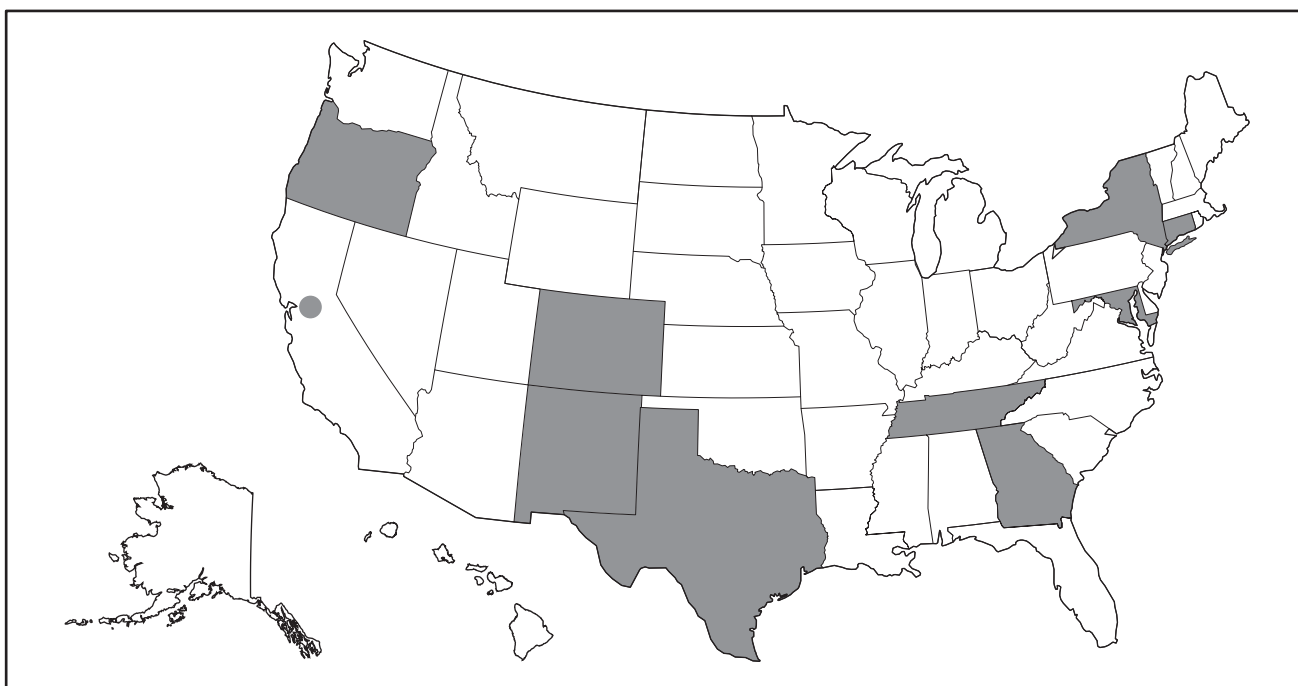

### PUBLIC HEALTH SURVEILLANCE

Public health surveillance is the continuous and systemic collection, analysis, interpretation, and feedback of systematically collected information used to inform public health decision making.<sup>22</sup> Timely community health information in the hands of trained experts is the foundation for recognition of threats to health. To intervene successfully to treat existing infections and prevent the onset of new ones, disease surveillance systems need to provide a continuous, accurate, and near real-time overview of a population's health. Surveillance systems must be sensitive in terms of their ability to detect outbreaks and other significant changes in community health status over time, and they must be flexible in adapting to changing health intelligence needs. Given the increasing pace of international travel and globalization and the threat of intentional outbreaks, surveillance activities need to extend beyond the monitoring of disease burden to include the capacity to quickly recognize unusual, unexpected, or unexplained disease patterns. Because many emerging infectious agents are zoonotic, it is also important to integrate veterinary disease reporting networks into systems that monitor diseases of humans.

Astute clinicians and microbiologists are essential for early detection of threats at the clinical front lines. In the United States, surveillance for notifiable diseases is conducted by state and local health departments, which receive reports from physicians, nurses, and laboratorians who are often the first to observe and report unusual illnesses or syndromes. States voluntarily report nationally notifiable diseases to the Centers for Disease Control and Prevention (CDC) through the National Electronic Telecommunications System for Surveillance (NETSS). To expedite national disease reporting, CDC, in collaboration with the Council of State and Territorial Epidemiologists (CSTE), has developed a standards-based system for collecting and distributing electronic disease reports from local health departments to state and federal public health authorities. The infectious disease surveillance component of this developing Public Health Information Network (PHIN) is the National Electronic Disease Surveillance System (NEDSS). NEDSS is designed to standardize and facilitate the collection of electronic disease information on nationally notifiable diseases within local health jurisdictions directly from health-care providers to local health authorities.<sup>23</sup> Limited resources have, however, precluded the establishment of a fully integrated health surveillance system that connects health departments and care providers.

Starting in 1994, CDC launched a two-phase initiative to strengthen domestic capacity to respond to the dual threats of endemic and emerging infections. The publication of

**FIGURE 15-1** Distribution of Emerging Infections Programs (EIPs), a network of state health departments and their collaborators in local health departments, academic institutions, and clinical settings, coordinated by the Centers for Disease Control and Prevention, 2004. Surveillance population: approximately 44 million.

two strategy documents<sup>24,25</sup> led to the launching of new surveillance initiatives, including the Emerging Infections Program (EIP), a national network for population-based surveillance and research<sup>26</sup> (Fig. 15-1). Several provider-based sentinel surveillance networks were established in collaboration with emergency room physicians, infectious disease specialists, and travel medicine specialists to provide early warning of events that might be missed by public health surveillance. Additional enhancements to the surveillance effort include development of the National Molecular Subtyping Network for Foodborne Disease Surveillance (PulseNet) as an early warning system for foodborne diseases, support for the Gonococcal Isolate Surveillance Project (GISP) to monitor antimicrobial resistance in *Neisseria gonorrhoeae*, strengthened surveillance for diseases of current concern (e.g., West Nile encephalitis), and surveillance for outbreaks that might be due to acts of bioterrorism.

The CDC also works in partnership with the World Health Organization (WHO), ministries of health, foundations, development agencies, and other federal agencies to promote national, regional, and international disease surveillance. Recognition of the global nature of the emergence and spread of infectious diseases stimulated the development of a third strategy document focused on CDC's efforts to enhance global capacity for disease surveillance and outbreak response.<sup>27</sup> The document presents six priority areas for protecting domestic and global health, among which are global initiatives for disease control, international outbreak assistance, and a global approach to disease surveillance. CDC's international activities include creation of the United States–Mexico Border Infectious Disease Surveillance (BIDS) system, development of the Global Emerging Infections Sentinel Network (GeoSentinel), and provision of technical assistance to regional disease

surveillance networks in Africa, Asia, Latin America, and the circumpolar regions of Canada and Europe, as well as to WHO's disease-specific global networks.

WHO manages global disease surveillance and response through a composite of partnerships and networks for gathering, verifying, and analyzing international disease intelligence, mainly to support global and regional efforts to eradicate certain diseases, such as polio, and to protect the global community against diseases with pandemic potential. The oldest of these networks is the global influenza surveillance network, which was established more than 50 years ago and has served as the prototype for the design and implementation of subsequent systems (see later discussion).<sup>28</sup> A recent addition to the disease-specific surveillance approach is DengueNet, a web-based network for gathering and sharing information on dengue and dengue hemorrhagic fever.

To respond to the increasing number of emerging and rapidly spreading infectious diseases, WHO has developed a global "network of networks" that links local, regional, national, and international networks of laboratories and medical centers into a mega-surveillance network for early warning and response.<sup>29</sup> Formal partners include ministries of health, WHO Collaborating Centers, WHO country and regional offices, and international military groups such as the Global Emerging Infections System of the U.S. Department of Defense (DoD-GEIS). Outbreak reports are also received from non-governmental organizations, relief workers, private clinics, individual scientists, and public health practitioners. Additional information is provided by Health Canada's Global Public Health Intelligence Network (GPHIN), an electronic tool used by WHO since 1997, which scans Internet news sites for reports of outbreaks and unusual disease events.

Global surveillance networks all operate within the framework of the International Health Regulations, which outline WHO's authority and member states' obligations in reporting and preventing the spread of infectious disease. The International Health Regulations require official reporting of only three diseases: plague, cholera, and yellow fever.<sup>30</sup> Outbreaks of these diseases are reported in WHO's *Weekly Epidemiological Record* and electronically through postings on the Internet. Recognizing the limitations of the regulations in the era of emerging and reemerging diseases and spurred by the SARS experiences of 2003, WHO and its member states have undertaken a revision of the document. During the 56th World Health Assembly (WHA), two resolutions were passed, one specific to SARS (WHA56.29) and the other adding impetus to the revision efforts (WHA56.28). The resolutions seek to secure enhanced collaboration with WHO in responding to infectious disease outbreaks. In recognition of the role of animals in the spread of human disease and the potential for infectious disease dissemination due to international travel and trade, the resolution prompted by the SARS experience also urges member states to "ensure collaboration, when appropriate, with veterinary, agricultural and other relevant agencies involved in animal care and research on, and planning and implementation of, preventive and control measures."<sup>31</sup>

Whereas the International Health Regulations provide the legal framework for global control of infectious diseases, WHO's Global Outbreak Alert and Response Network (GOARN) is the operational arm, that is, the mechanism by which WHO's partners respond to outbreaks of international

importance.<sup>29</sup> GOARN activities are described in the following section.

## EXAMPLES OF SPECIALIZED SURVEILLANCE AND RESPONSE NETWORKS

### Global Influenza Surveillance Network

Established in 1952, this global network of more than 100 virus laboratories in 83 countries monitors influenza activity and collects the viral isolates that determine the composition of the following year's influenza vaccines<sup>32</sup> (Fig. 15-2). The isolates are characterized by WHO Collaborating Centers in the United Kingdom, Japan, Australia, and the United States. In addition to guiding the annual composition of recommended vaccines, the network operates as an early warning system for the appearance of influenza variants and novel strains that could signal the emergence of an influenza pandemic.

### Global Laboratory Network for Poliomyelitis Eradication

International disease eradication strategies include a strong surveillance component. To support the Global Polio Eradication Initiative, WHO established the Global Laboratory Network for Poliomyelitis Eradication,<sup>33</sup> which uses molecular techniques to determine whether wild-type polio is circulating in areas undergoing eradication efforts. Genomic sequencing capabilities and collaboration among network laboratories have allowed the tracking of virus

**FIGURE 15-2** Countries with at least one World Health Organization (WHO) influenza virus laboratory. The black dots represent the sites of the WHO collaborating centers for influenza, in Atlanta, London, Tokyo, and Melbourne.

strains within and among countries and the identification of the origin of viruses imported into polio-free countries.<sup>34</sup>

### **Global *Salmonella* Surveillance System (Global Salm-Surv)**

Started in 2000, WHO's Global Salm-Surv is a global network of laboratories and individuals involved in isolation, identification, and antimicrobial resistance testing of *Salmonella* and surveillance of salmonellosis. The goal is to enhance the capacity and quality of *Salmonella* surveillance, serotyping, and antimicrobial resistance testing throughout the world. Global Salm-Surv conducts an electronic discussion group, international training courses for microbiologists and epidemiologists, external quality assurance testing, and focused research projects on topics such as surveillance enhancement and burden of illness. Member institutions enter their top 15 *Salmonella* serotypes yearly in a web-based country databank that can be searched for serotype frequency nationally, regionally, or globally.

### **Global Project on Antituberculosis Drug Resistance Surveillance**

Surveillance of antimicrobial resistance is fundamental for understanding trends, developing treatment guidelines, and assessing the effectiveness of interventions. In 1994, WHO, the International Union against Tuberculosis and Lung Disease (IUATLD), and other partners launched the Global Project on Antituberculosis Drug Resistance Surveillance in response to growing concern about drug resistance and its impact on TB control. The purpose of this network of reference laboratories is to measure the prevalence of anti-TB drug resistance in several countries using standard methods and to study the correlation between the level of drug resistance and treatment policies in those countries.

### **Global Outbreak Alert and Response Network**

GOARN was launched in 2000 as a mechanism for combating international disease outbreaks, ensuring the rapid deployment of appropriate technical assistance to affected areas, and contributing to long-term epidemic preparedness and capacity building. GOARN electronically links more than 120 partner institutions and surveillance networks, which together possess the expertise, skills, and resources for rapid outbreak detection, verification, and response.<sup>29</sup> The coordinated response to the large Ebola hemorrhagic fever outbreak in Uganda in 2000 demonstrated the merit of the principles on which the network is based and functions.<sup>18,35</sup> The importance of GOARN was also evident in 2003, when WHO coordinated the unprecedented global response to SARS. Through GOARN, WHO mobilized the international public health, clinical, and research communities to rapidly identify and characterize the causative agent and to contain the spread of this new infectious agent, providing a new standard for future responses to global microbial threats.<sup>36</sup>

### **Laboratory Response Network**

The Laboratory Response Network (LRN) was established by CDC in 1999 to respond quickly to acts of chemical and

biological terrorism, emerging infectious diseases, and other public health threats and emergencies. The more than 120 federal, state, and local public health, veterinary, military, environmental, and international laboratories in the network have progressively stringent levels of safety, containment, and technical proficiency that enable them to recognize, rule out, confirm, or definitively characterize highly infectious agents using standardized protocols and reagents and to maintain communication through a secure web site.

The value of the LRN was demonstrated during the SARS epidemic, when validated reagents and protocols were rapidly distributed within weeks of the discovery of the etiologic agent (SARS-associated coronavirus [SARS-CoV7]) thereby providing diagnostic testing capability to each state.

## **CRITICAL ROLE OF THE LABORATORY**

Microbiology laboratories play a critical role in surveillance for emerging infectious diseases and bioterrorism threats by identifying the microbial cause of syndromes, detecting and reporting new or unusual pathogens, and assessing antimicrobial resistance.<sup>6,37</sup> To carry out this role, laboratories require well-equipped and safe facilities, adequate human and financial resources, access to needed reagents, and robust quality control.

Accurate etiologic diagnosis is dependent on standardization of and scrupulous attention to a series of essential procedures. These include the collection of appropriate clinical specimens, careful handling of specimens, accurate and complete labeling, and access to relevant clinical information to guide the testing process. Laboratorians also benefit from knowledge of the local epidemiologic situation. The chain of events is completed when the laboratory provides results to the attending medical staff to guide clinical management of the patient and to the epidemiologist for trend analysis, monitoring, and response. Specimen collection requires an understanding of the samples needed (e.g., whole blood, serum, cerebrospinal fluid); proper containers for safe transport outside the clinical facility; complete labeling with information on the source and the time of collection relative to clinical status; proper packaging for shipping; and compliance with regulations for transport. The laboratory to which the specimens are being sent should be notified in advance about the shipment to facilitate assistance with customs clearance and transport.

The critical needs of the laboratory center around three basic resources: equipment and supplies to conduct the required tests, reagents to test for the pathogens of interest, and trained staff to perform the testing. Although each of these requirements may be a limiting factor in the recognition of emerging infections, the availability of high-quality diagnostic reagents may be the most critical, especially for viral diseases. Laboratories often have adequate reagents for diseases known to occur locally but not for viral illnesses that occur in other parts of the world. Ensuring the quality of serologic tests also requires inclusion of positive and negative control sera that might be difficult to obtain, especially for diseases of low incidence. If reagents are not commercially available, the laboratory must rely on its own locally produced reagents or on reagents supplied by others that may not have benefited from appropriate quality control during production.

For some agents, such as influenza, dengue, and hantaviruses, commercially available diagnostic kits that can be used in settings with minimal laboratory facilities have overcome this obstacle. Nonetheless, the user, who may not be a trained laboratorian, still needs to collect the specimen appropriately and interpret the results correctly.

One of the most important aspects of a global strategy for monitoring of emerging diseases, especially those caused by viruses, is ensuring the proper level of biosafety containment and strict adherence to biosafety procedures to allow safe handling of pathogenic organisms. The importance of biosafety precautions was demonstrated by the recurrence of SARS-CoV in Singapore, Taiwan, and China in late 2003 to early 2004 due to laboratory acquired infections.<sup>38–40</sup> Most organisms are classified in one of four distinct biosafety levels, depending on the seriousness of the disease they produce, their transmissibility, and the availability of effective treatment or vaccines.<sup>41</sup> Biosafety levels 3 and 4 are required for handling the most dangerous pathogens and require highly specialized facilities. The physical plant required to support a biosafety level 4 laboratory is considerable, and maintenance expenses are high. Consequently, only a few exist in the world, and all serve as major referral laboratories.

Laboratory diagnosis is not confined, however, to state-of-the-art facilities. The use of field laboratories can be a factor in the rapid containment of outbreaks of emerging infectious diseases. During the 2000–2001 outbreak of Ebola hemorrhagic fever in Uganda, laboratory testing was performed at a field laboratory established by CDC and supplemented by additional testing at CDC and other reference centers.<sup>18</sup> The availability of the field lab was determined to be a key logistic element in containing the outbreak rapidly.<sup>42</sup>

Pathology laboratories also make critical contributions to the identification of new and emerging infectious diseases.<sup>43</sup> Pathologists have had a frontline role in identifying the causal agents, describing the pathogenetic processes, and guiding the early phases of the epidemiologic investigations of several recently described diseases, including hantavirus pulmonary syndrome,<sup>44</sup> new variant Creutzfeldt-Jakob disease,<sup>45</sup> and SARS.<sup>46</sup> Clinicopathologic studies have also been useful in delineating the pathogenesis of emerging infectious diseases such as West Nile virus encephalomyelitis.<sup>47</sup> Immunologic and molecular methods, including immunohistochemistry (IHC), in situ hybridization, and polymerase chain reaction (PCR), have revolutionized the ability of pathologists to diagnose and study infectious diseases and are likely to ensure an increasing role of pathology as an active partner in surveillance activities.<sup>43</sup>

## COMMUNICATIONS

A final component of surveillance is the ability to rapidly and reliably exchange information on disease incidence and distribution, preferably in real time. Disease intelligence relies on formal and informal networks for dissemination and sharing of timely, accurate information on occurrences and outbreaks of infectious diseases and diffusion of prevention recommendations. One of the key lessons that emerged from the 2003 global SARS epidemic was the importance of networks of laboratory scientists, clinicians, and public health experts, aided by electronic communications, in rapidly generating the

scientific basis for public health action. It was the “virtual” international network of laboratories, linked by a secure web site and daily teleconferences, that identified the causative agent and developed early diagnostic tests. The laboratory network served as a model for groups of clinical and epidemiologic experts who shared and compiled the data needed to track the outbreak and assess the effectiveness of containment measures.

In the current electronic era, countries are increasingly aware of the value of network-facilitated early warning systems, rapid information exchange, and technology transfer for the control of infectious agents. Technologies developed and enhanced over the last several years have stimulated the creation of web-based public health tools for improving national and international disease reporting and facilitating emergency communications. In the United States, CDC communicates breaking surveillance information to public health officials through two electronic networks: the Epidemic Information Exchange (Epi-X), a secure mechanism for sharing health surveillance information on outbreaks and other unusual events, and the Health Alert Network (HAN), which links local, state, and federal health agencies and provides an electronic platform for emergency alerts and long distance training. In similar fashion, the Eurosurveillance Project, funded by the European Commission, promotes the diffusion and exchange of information on communicable diseases in Europe. Globally, WHO shares information through the Outbreak Verification List distributed weekly by electronic mail, the WHO Disease Outbreak News on the WHO web site, and the *Weekly Epidemiological Record*. Supplementing these mechanisms are less formal networks of individuals and organizations, such as GPHIN, the web-based application that scans global electronic news media for information on health risks and the Program for Monitoring Emerging Diseases (ProMED), a web-based reporting system.

Another essential component of information exchange during infectious disease outbreaks is risk communication. Any outbreak of a novel or reemerging infectious disease is likely to be characterized by scientific uncertainties and high levels of concern that public health officials will be challenged to harness and guide. Since the 2001 anthrax attacks and the 2003 global SARS outbreaks, CDC and WHO have been actively involved in efforts to incorporate risk communication into public health practice.

## SUMMARY

Future challenges posed by infectious agents are difficult to predict but certainly include the continuing threat of an influenza pandemic, a recurrence of SARS, the emergence of other zoonotic agents that cross the species barrier to humans, the emergence of new bacterial strains that are more virulent or resistant to antibiotics, the possible deliberate release of pathogenic microbes by terrorists, and the likelihood of increased spread of dengue, cholera, West Nile virus, yellow fever, and foodborne diseases. The best defense against these mobile and resilient pathogens is timely and reliable infectious disease information obtained through global public health surveillance.<sup>29</sup> The international community has made important strides in developing networks for detecting and reporting infectious disease events and enhancing capacity for

clinical and laboratory surveillance. Continued commitment and support are needed to optimize the use of these systems to improve the detection of unusual disease events, strengthen the ability to share disease intelligence, and inform prevention and containment efforts.

### INTRODUCTION

Diarrheal illnesses constitute one of the leading infectious causes of death and disability worldwide. It is estimated that approximately 2.5 million children die annually from diarrheal illnesses, the vast majority in Africa, Asia, and Latin America.<sup>1</sup> In a World Bank index of overall disease burden, disability-adjusted life years (DALYs) lost, diarrheal illnesses accounted for 7.3% of the total DALYs lost worldwide in 1990, nearly twice that due to sexually transmitted diseases, including acquired immunodeficiency syndrome (AIDS), and three times that due to malaria.<sup>2</sup> Furthermore, the World Bank DALY calculation for diarrhea counts predominantly its mortality, largely ignoring its even more staggering impact on morbidity and malnutrition.<sup>3</sup> Of the varied bacterial pathogens known to cause diarrhea worldwide, enterovirulent *Escherichia coli* collectively constitutes one of the most common, if not the most common, causes of diarrheal illness in tropical regions, particularly where sanitation facilities are limited.<sup>4-6</sup>

*E. coli* is the major aerobic organism of the normal intestinal flora, with around  $10^{6-8}$  colony-forming units per gram of stool. Although the majority of isolates remain nonpathogenic gut commensals, diverse sets of virulence determinants confer this versatile species with virtually the entire range of pathogenic mechanisms by which bacteria cause diarrhea. Depending on how one deconstructs the complex range of diarrheagenic virulence traits in *E. coli*, anywhere between 5 and 10 different categories can easily be defined. This chapter emphasizes the five major types for which pathogenicity in

outbreaks or volunteer studies has been established: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), enterohemorrhagic *E. coli* (EHEC), and enteroinvasive *E. coli* (EIEC). Also reviewed is diffusely adherent *E. coli* (DAEC), which has been variably associated with diarrhea in epidemiologic studies.

### AGENT

*E. coli* is a short, non-spore-forming, often fimbriate gram-negative bacillus that grows readily on simple culture media or synthetic media with as little as glycerol or glucose as its only nutrient. With the exception of many enteroinvasive strains, most *E. coli* organisms are first identified as lactose-fermenting gram-negative rods on routine culture medium. Other biochemical characteristics include indole production, lack of citrate fermentation, positive methyl red test, and negative urease and Voges-Proskauer reactions. *E. coli* is further characterized by a relatively complex serotyping scheme involving 173 O (lipopolysaccharide), 80 K (capsular), and 56 H (flagellar) antigens, all of which can be subdivided into partial antigens. Although the final number of *E. coli* serotypes is enormously high, 50,000 to 100,000 or more, the number of pathogenic serotypes in gastrointestinal infections is fairly limited (Table 16-1). The current serotyping scheme

**Table 16-1 Serogroups Associated with Enterovirulent *Escherichia coli***

Category	Predominant O Serogroups
Enterotoxigenic (ETEC)	LT: 1, 6, 7, 8, 9, 128 LT + ST: 11, 15, 20, 25, 27, 60, 63, 75, 78, 80, 85, 88, 89, 99, 101, 109, 114, 139, 153 ST: 12, 78, 115, 148, 149, 153, 159, 166, 167
Enterohemorrhagic (EHEC)	157, 26, 103, 111, 113, + some 50 others
Enteroinvasive (EIEC)	11, 28, 29, 112, 115, 124, 136, 143, 144, 147, 152, 164, 167, 173
Enteropathogenic (EPEC)	18, 26, 44, 55, 86, 111, 114, 119, 125, 126, 127, 128, 142, 145, 157, 158
Enteroaggregative (EAggEC)	3, 15, 44, 51, 77, 78, 86, 91, 92, 111, 113, 126, 141, 146
Diffusely adherent (DAEC)	75, 15, 126

establishes O and H antigens based on bacterial agglutination; the K antigen is determined by gel immunoprecipitation or phage typing.<sup>7</sup> Each of the major categories of diarrheagenic *E. coli* falls into a relatively, but not absolutely, restricted set of these O:H serotypes, which has proved useful in understanding both the pathogenesis and epidemiology of enteric *E. coli* infections.

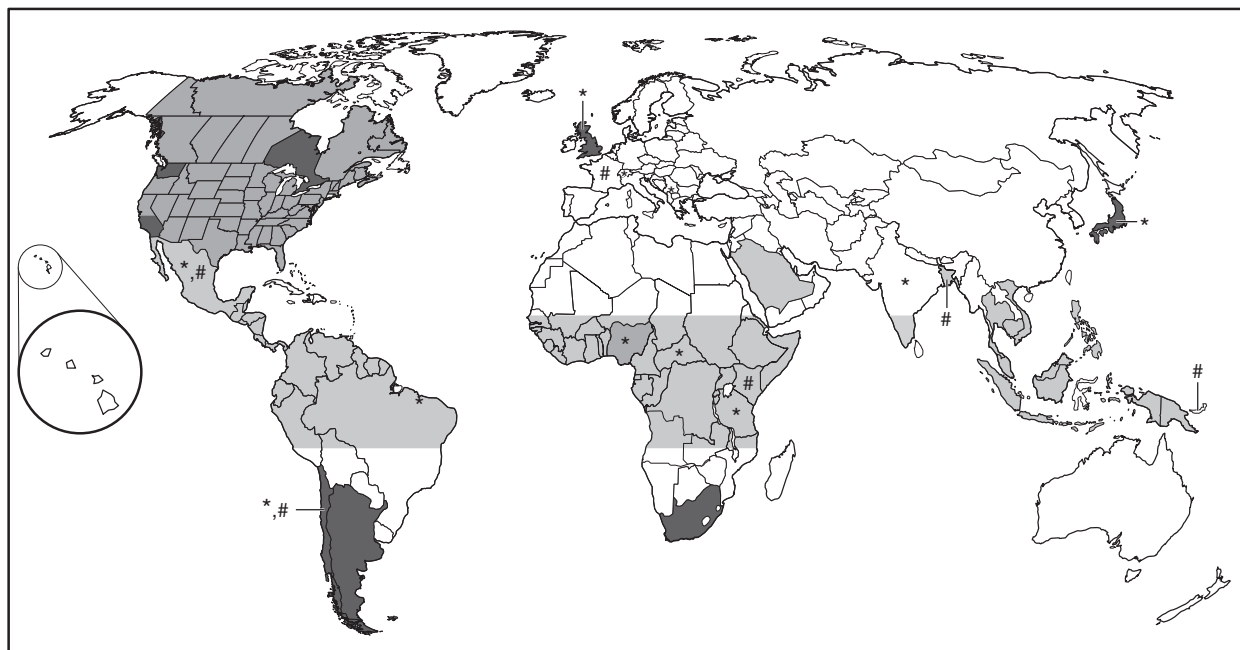

## EPIDEMIOLOGY

Despite the worldwide ubiquity of *E. coli*, most enteric *E. coli* infections are seen in the developing world where sanitation facilities are limited. In community-based studies in Bangladesh and Brazil, ETEC alone accounted for up to 15% to 20% of cases of diarrhea<sup>4,8</sup> and, overall, ETEC is regarded as the leading identified cause of traveler's diarrhea,<sup>9,10</sup> having been isolated in over half of the cases investigated in some studies.<sup>11,12</sup> Young children in the tropics are particularly prone to ETEC infections. In one prospective longitudinal study, ETEC was identified as the cause of diarrhea as many as two to three times per year per infant.<sup>13</sup> Like most enteropathogens, ETEC infection is acquired by ingesting contaminated food or water, and infants are at particular risk at weaning. The infective dose of ETEC is relatively high in the normal host, ranging from  $10^6$  to  $10^{10}$  colony-forming units.<sup>14,15</sup>

EPEC was the first group of *E. coli* shown to cause diarrhea. In the 1940s, epidemiologic investigations implicated EPEC

isolates in outbreaks of community-acquired and nosocomial infantile diarrhea in Great Britain.<sup>16</sup> In these initial reports, mortality rates exceeded 50% in some cases.<sup>16</sup> Although EPEC is no longer considered a common cause of diarrhea in most developed nations, sporadic cases and outbreaks have been reported in Great Britain, Finland, and the United States.<sup>17–21</sup> Numerous studies in tropical or developing areas have demonstrated a convincing association of EPEC in infants with diarrhea,<sup>21–26</sup> and in some studies EPEC was identified as the most common bacterial cause of diarrhea in the youngest children.<sup>26–28</sup> Recent hospitalization has been identified as an important risk factor for EPEC diarrhea in children in São Paulo, Brazil.<sup>21</sup> Older studies have suggested bottle feeding as a risk factor for EPEC diarrhea,<sup>16,29</sup> and more recent series have demonstrated that breastfeeding is protective.<sup>21,28</sup>

EAEC, classically identified by its ability to adhere to HEp-2 cells and glass slides in a “stacked-brick” pattern, is implicated as a significant cause of persistent diarrhea (greater than 14 days) in developing regions (identified on the map with an asterisk [\*]).<sup>22,30–33</sup> This endemic pediatric diarrhea was initially felt to be the predominant disease caused by EAEC, but more recent studies have demonstrated that EAEC is nearly as common as ETEC as a potential cause of adult travelers' diarrhea and also causes outbreak and episodic infections in developed countries.<sup>34–38</sup> EAEC has also been identified as a cause of chronic diarrhea in patients with AIDS.<sup>39–42</sup>

### Enteric *Escherichia coli*

■ Enterohemorrhagic *E. coli* (EHEC), more prevalent in industrialized regions, but outbreaks also have been recognized in South Africa and Swaziland.

■ Major outbreaks of EHEC.

■ Enterotoxigenic *E. coli* and enteropathogenic *E. coli*, more prevalent in developing, tropical regions.

*Note:* A number of epidemiologic studies have linked enteroaggregative *E. coli* (\*) or diffusely adherent *E. coli* (#) with either acute or persistent diarrhea.

Diffusely adhering *E. coli*, so named because of its HEP-2 pattern of adherence, has been variably associated with diarrhea in a number of epidemiologic studies (identified on the map by the number mark [#]).<sup>25,43–47</sup> In the largest of these, Levine and colleagues<sup>46</sup> examined 1081 samples from children with diarrhea and matched controls in Chile. An association between DAEC and diarrhea increased with age, plateauing at a relative risk of 2.1 at 48 to 60 months of age. The increasing list of epidemiologic studies that examine the importance of EAEC and DAEC in pediatric diarrhea is exhaustive; the reader is referred to several excellent reviews for a comprehensive summary.<sup>48–50</sup>

Although infection with *E. coli* O157:H7 and other EHEC is primarily recognized in developed countries, this pathogen also occasionally plagues the developing world. The majority of outbreaks worldwide are reported in the United States, Canada, the United Kingdom, and Japan, where foods originating from or contaminated by bovine sources are typically implicated.<sup>51–54</sup> EHEC has also been isolated in a number of tropical or developing areas, including Chile, Argentina, India, South Africa, and Swaziland.<sup>55–58</sup> Like most of the other enterovirulent *E. coli*, sporadic cases of *E. coli* O157:H7 peak during the warm weather months.<sup>59</sup>

EIEC, which taxonomically is more closely related to *Shigella* than to other *E. coli*, probably accounts for only 1% to 2% of endemic diarrheal episodes.<sup>60</sup> EIEC infections can be readily transmitted via contaminated food, and the largest outbreak (226 persons affected) in the United States was attributed to contamination of imported Camembert cheese with EIEC serogroup O124.<sup>61</sup>

## CLINICAL MANIFESTATIONS

Dictated by diverse sets of virulence determinants, the clinical manifestations of the different types of enterovirulent *E. coli* vary from cholera-like watery secretion with ETEC to dysentery indistinguishable from shigellosis with EIEC. The clinical characteristics of various enteric *E. coli* infections are summarized in Table 16-2. ETEC characteristically causes an acute watery diarrhea within 8 to 72 hours after ingestion, which ranges from a mild self-limited illness to dehydrating cholera-like purging.<sup>14,15</sup> Typically, stools are watery and without evidence of inflammation. Fever is usually low-grade or absent. Beyond the diarrhea, ETEC infections in infants and children interrupt normal feeding patterns and lead to diminished long-term linear growth.<sup>4,13</sup>

EPEC infections can be devastating to the neonate. Classically, mortality rates of 25% to 70% have been reported in outbreaks where clinical illness is typically characterized by vomiting, low-grade fever, and profuse watery diarrhea. In subjects with experimental EPEC infection, fecal lactoferrin levels are significantly elevated, demonstrating the inflammatory nature of this disease.<sup>62</sup> EPEC may persist, as evidenced in a U.S. day-care center outbreak in which infants' symptoms lasted for a mean of 18 days.<sup>17</sup>

EAEC is prominently linked with persistent diarrhea in children. Fever and grossly bloody stools are rarely associated with clinical infection,<sup>22,31</sup> but fecal lactoferrin levels are often elevated in children with EAEC infections whether they have diarrhea or not, the latter having significant growth shortfalls,

suggesting that EAEC causes malnutrition and intestinal inflammation, with or without diarrhea.<sup>63</sup> It is notable that in some epidemiologic studies EAEC has not been associated with diarrhea<sup>43,47,64</sup> and that different strains have variably caused diarrhea in human volunteer studies.<sup>65,66,66A</sup> This observation is partly explained by heterogeneous expression of virulence determinants, but host factors may also be relevant. It was recently shown that travelers with a particular genotype in the interleukin (IL)-8 promoter are more likely to develop symptomatic diarrhea with EAEC infection. The importance of this and other naturally occurring polymorphisms in EAEC infection in other settings remains to be known.

Little is known about the clinical characteristics of DAEC enteric infections, which have been inconsistently associated with diarrhea (except in older children 18 to 60 months of age). One study found a particular association of DAEC with vomiting.<sup>67</sup> However, its pathogenicity is clouded by two studies involving 51 volunteers challenged with three different DAEC strains.<sup>65,68</sup> Only one individual developed diarrhea. As with EAEC, not all DAEC isolates (as defined by HEP-2 adherence) possess the necessary virulence traits to cause disease. For example, in one case-control study, only DAEC isolates that expressed the *afa* locus were statistically associated with diarrhea.<sup>69</sup>

*E. coli* O157:H7 and other EHEC cause diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), and sometimes death. Although infection with *E. coli* O157:H7 typically begins as nonbloody diarrhea, in most cases that come to medical attention the diarrhea becomes bloody by the second or third day of illness. Fevers are seen in fewer than one-third of patients and vomiting in about half. Fecal leukocytes or lactoferrin are typically seen in less than 40% of patients with symptomatic EHEC infection. Uncomplicated infections typically resolve in about 1 week. Infection with *E. coli* O157:H7 has been confused with a number of other gastrointestinal disorders such as appendicitis, inflammatory bowel disease, and ischemic colitis.<sup>51,70</sup> Local complications may include bowel perforation, toxic megacolon, and stricture.<sup>59,70,71</sup> The most devastating sequela, HUS (a constellation of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure), occurs most frequently in children between 1 and 4 years of age and in the elderly.<sup>72</sup> The overall rate of HUS in sporadic cases of bloody diarrhea with *E. coli* O157:H7 is between 5% and 10%.<sup>59</sup> A number of studies point to pre-existing EHEC infection in 75% to 95% of children presenting with HUS.<sup>73–76</sup> It is often difficult to document microbiologic evidence of EHEC infection at the onset of HUS symptoms, as persons with HUS typically seek medical attention around 6 to 12 days after the onset of diarrhea, when the EHEC stool counts are decreasing.<sup>77</sup> Reported risk factors for the development of HUS in patients with EHEC diarrhea include the extremes of age,<sup>78</sup> leukocytosis,<sup>79</sup> diminished P1 antigen expression on red blood cells,<sup>80</sup> the use of antimotility agents, and possibly prior antimicrobial therapy (see later discussion).<sup>51,81</sup>

As with shigellosis, EIEC infection typically causes watery diarrhea, followed by dysenteric stools with mucus, fecal leukocytes, and scant blood. Fever, severe abdominal cramps, and malaise are common.

Table 16-2 Clinical Features of Enteric *Escherichia coli* Infections

Type of <i>E. coli</i>	Epidemiology/Setting	Incubation Period	Diarrhea	Additional Features	Sequelae
ETEC	Young children to adults in developing world	10–72 hr	Acute watery	Nausea, abdominal cramping; with or without low grade fevers	Interrupted feeding patterns leading to diminished linear growth
EPEC	Travelers to tropics Infants in developing world	As short as 9–12 hr	Acute persistent Watery	Positive fecal lactoferrin, vomiting, fever, dehydration	Mortality rates up to 25%–70% reported
EAEC	Children in developing world	20–48 hr	Persistent	Fever in 12%; grossly bloody stools in up to one third of patients	May interfere with normal growth patterns
	Travelers to tropics	Unknown	Acute; occasionally persistent	More likely than ETEC to have positive fecal lactoferrin	Occasional persistence
EHEC	All ages Primarily in United States, Canada, Europe, cone of South America	12–60 hr	Acute bloody diarrhea (progressing to hemorrhagic colitis in 38%–61%); occasionally nonbloody diarrhea	Fecal leukocytes or lactoferrin in 30%–40%; Fevers in 0%–32%; abdominal pain; moderate leukocytosis	Progression to HUS/TTP in 2%–8%; rarely death; complications greatest at extremes of age; Long-term renal damage may occur following HUS
EIEC	All ages Primarily in developing regions; occasional outbreaks in industrialized countries	As short as 10–18 hr	Acute watery diarrhea followed by dysentery	Fecal leukocytes or lactoferrin elevated; gross purulence, blood, mucus may be seen in stool; severe abdominal cramps	Hypoglycemia, especially if malnourished
DAEC	Pathogenicity most established in children ages 24–60 months	Unknown	Acute in 3 studies; persistent in 1; not associated with diarrhea in multiple studies	Nausea/vomiting prominent in one study	Unknown

HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

## PATHOGENESIS AND IMMUNITY

Summarized in Table 16-3 are the major known virulence determinants for enterovirulent *E. coli*, including their genetic traits, mechanisms of action, and relevant experimental models. Also noted are other enteric bacteria expressing similar virulence determinants, illustrating that the diverse range of virulence traits demonstrated in *E. coli* infections are representative of those present in the majority of bacterial enteropathogens. While not dealt with elsewhere in this book, such organisms as *Aeromonas*, *Plesiomonas*, *Klebsiella*, *Citrobacter*, *Enterobacter*, and *Yersinia* may produce enterotoxins, as noted in Table 16-3, and may be important enteric pathogens, more often in cooler, temperate climates.

### Enterotoxigenic *E. coli*

In order for ETEC to be fully pathogenic, the organism must both colonize the small intestine and elaborate one or more enterotoxins. After ingestion in contaminated food or water, ETEC with fimbrial colonization factor antigens (CFAs) attach and multiply in situ, thereby overcoming the peristaltic defense mechanism in the proximal small intestine. CFA-I, CFA-II, CFA-IV, and others are distinguished from the type 1 pili, common to almost all *E. coli*, by their ability to agglutinate erythrocytes in the presence of D-mannose. Although most ETEC isolates are associated with at least one of the classic CFA types, other additional attachment factors (such as PCFO159,

PCFO166, E8775, CS 7, and CS 17), yet to be fully characterized, may also participate in small intestine colonization.<sup>82-85</sup>

ETEC is defined primarily by the heat-labile (LT) and heat-stable (ST) toxins it elaborates. Of the four known enterotoxins (LT-I, LT-II, STa, and STb) produced by ETEC, LT-I and STa are best established as important secretagogues in humans, and pathogenic strains typically elaborate one or both of these toxins. The LT-I family of toxins are high-molecular-weight proteins (84,000 to 86,000 daltons) remarkably similar to cholera toxin in structure and function. The deduced amino acid sequences of the single enzymatically active (A) subunit and the five binding (B) subunits of LT-I demonstrate approximately 80% homology with that of cholera toxin, and its secretory effect is blocked by antisera to cholera toxin.<sup>86</sup> Given this degree of structural similarity with cholera toxin, it is not surprising that the mechanism of action of LT enterotoxin is nearly identical to that of cholera toxin (Fig. 16-1). After binding to a GM<sub>1</sub> ganglioside receptor (or to a 130- to 140-kDa glycoprotein receptor 20 to 30 times more prevalent in intestinal brush border than the binding site for cholera toxin<sup>87</sup>) like cholera toxin, LT activates adenylate cyclase via NAD-dependent adenosine diphosphate (ADP) ribosylation of Gs $\alpha$ . The resultant increase in intracellular cyclic adenosine monophosphate (cAMP) ultimately stimulates chloride secretion and inhibits sodium absorption, leading to the voluminous watery stools characteristic of this infection. The ST toxin family, which bears significant homology with

**FIGURE 16-1** Heat-labile toxin (LT), a homologue of cholera toxin, binds to a monosialoganglioside receptor (GM1) via its B subunits, and the A<sub>1</sub> subunit is released from B<sub>5</sub> and A<sub>2</sub> by cleavage of a disulfide bond. This enzymatically active peptide catalyzes the dissolution of NAD to nicotinamide and, in the presence of adenosine diphosphate (ADP) ribosylation factors (ARFs), ADP ribosylates Gs $\alpha$ , which then dissociates from the  $\beta\gamma$  subunit to activate adenylate cyclase. Cyclic adenosine monophosphate (cAMP) formation, catalyzed by adenylate cyclase, stimulates water and electrolyte secretion by intestinal epithelial cells via protein kinase A, prostaglandin (PG) synthesis, and possibly platelet-activating factor (PAF). ATP, adenosine triphosphate; GTP, guanosine triphosphate.

Table 16-3 Pathogenic Mechanisms of Enterovirulent *Escherichia coli*

Category*	Virulence Determinant	Genetic Locus	Mechanism	Experimental Model	Enteric Bacteria Expressing Similar Virulence Determinants
ETEC†	CFA-I-IV LT I and II	Plasmid LT-I (plasmid) LT-II (chromosome)	Colonization Adenylate cyclase → secretion	MRHA 18-hr rabbit ileal loops and CHO/Y1 cells	LT-like toxins: <i>Vibrio cholerae</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Aeromonas hydrophila</i> , <i>Plesiomonas shigelloides</i> , <i>Campylobacter</i> , <i>Salmonella</i>
	ST-I (ST <sub>a</sub> )	Plasmid	Guanylate cyclase → secretion	4–6 hr rabbit ileal loops and suckling mice	ST-like toxins: <i>Yersinia</i> <i>enterocolitica</i> , <i>Citrobacter freundii</i> , non-O1 vibrios, EAEC
	ST-II (ST <sub>b</sub> )	Plasmid	Cyclic nucleotide– independent HCO <sub>3</sub> secretion	Piglet loop	
	SLT-I and II SLT-II <sub>vh</sub> and II <sub>vp</sub>	Phage	Toxins bind to Gb3 receptor; Glycosidase cleaves adenosine- 4324 in 28S rRNA of 60S ribosomal subunits to halt protein synthesis	HeLa cell cytotoxicity	Shiga toxin: <i>Shigella dysenteriae</i> type I
EHEC†	Intimin	Locus of enterocyte effacement (LEE) (chromosomal pathogenicity island)	Intimate adherence to Tir (see below), leading to pedestal formation	Fluorescent actin staining (FAS), pedestal formation	EPEC, <i>Citrobacter rodentium</i> , REPEC
	Type III secretion system (TTSS)	LEE	Intimate attachment via Tir injected into cell membrane; actin rearrangement, pedestal formation		EPEC shares many similar genes, although pedestals are qualitatively different; TTSS found in many plant and animal pathogens (e.g., REPEC, <i>Citrobacter rodentium</i> , <i>Salmonella</i> , <i>Yersinia</i> )
	TTSS effectors: Tir	LEE	Binding to intimin, recruitment of actin condensation		
	EspA EspB,D	LEE LEE	Part of needle complex Form pores in host cell membrane for effector delivery		
	EspF EspG, H Map NleA	LEE LEE LEE Non-LEE PAI	Causes host cell apoptosis Possibly mediates invasion Mitochondrial damage Target unknown; localizes to Golgi apparatus		
	Accessory toxins: ToxB EspP Ehx (RTX toxin) StcE	pO157 plasmid	Implicated in adhesion, cytotoxicity, tissue edema	Various	Homologues in many pathogenic bacteria

EIEC <sup>†</sup>	IpaA, B, C IpgD (invasion and adhesin proteins) IsaA	Plasmid  Plasmid	Cell invasion and spread Actin nucleation, leading to intracellular spread	Séreny test  Actin microfilament formation and cytoplasmic motility	Invasion plasmid: <i>Shigella</i> spp.  <i>Shigella</i> spp.
EPEC <sup>†</sup>	SepA  Bundle-forming pilus  Intimin/Tir	Plasmid  60-MDa EAF plasmid (bfpA) Chromosomal LEE	Serine protease autotransporter (SPATE) Localized adherence (LA)  Tir injected into host cell gets tyrosine phosphorylated and binds intimin on bacterial surface Similar effectors as in EHEC, above Motility: IL-8 release via TLR5 activation	LA to HEp-2 cells  FAS, pedestal formation	Various  EHEC, <i>Citrobacter rodentium</i> , REPEC
EAE <sup>†</sup>	TTSS  flagellin  Aggregative adherence fimbriae (AAF)	LEE, additional PAIs <i>fliC</i> (chromosome)  <i>aggA</i> (60-MDa AA plasmid)	Guanylate cyclase → secretion Regulated deaggregation during colonization Cleavage of fodrin, leading to cytoskeletal damage Mucinase	Motility and cytokine release  HEp-2 or HeLa cell AA  Rabbit ileal loops and Ussing chambers  Ussing chamber; cytotoxicity	<i>Salmonella</i> , EAEC, EHEC  Found in many EHEC, other <i>E. coli</i>  Other SPATE family members
DAEC	EAST1  Dispersin  Pet  Pic  ShET-1  flagellin  Fimbrial adhesin (F1845)  Afimbrial adhesin (AIDA-1)	<i>astA</i> (AA plasmid) <i>aap</i> (AA plasmid) Plasmid  <i>pic/set</i> locus on chromosome <i>pic/set</i> locus on chromosome <i>fliC</i> (chromosomal) Chromosome  Plasmid	Possible enterotoxin  IL-8 release via TLR5 activation Binding to CD55 (decay accelerating factor) leading to unique cytopathology DA	Ussing chamber  Motility, cytokine release Diffuse adherence (DA) to HEp-2 cells  DA to HEp-2 cells	<i>Shigella</i>  <i>Salmonella</i> , EPEC, EHEC  Uropathogenic <i>E. coli</i>

CFA, colonization factor antigen; LEE, locus of enterocyte effacement; LT, heat-labile toxin; MRHA, mannose-resistant hemagglutination; PA1, pathogenicity island, REPEC, rabbit enteropathogenic *E. coli*; SLT, Shiga-like toxin; ST, heat-stable toxin.

\*See Table 16-1.

<sup>†</sup>Pathogenicity in humans established in outbreaks or volunteer studies.

**FIGURE 16-2** Heat-stable enterotoxin (ST), an 18- to 19-amino acid peptide, binds to an extracellular domain of guanylate cyclase (GC-C) to increase cyclic guanosine monophosphate (cGMP), which activates G kinase, ultimately leading to altered sodium and chloride transport via phosphorylation of membrane proteins. GTP, guanosine triphosphate.

the endogenous intestinal peptide guanylin, also causes fluid and electrolyte secretion.<sup>88</sup> The major ST toxin responsible for diarrhea in humans, STa, is an 18- to 19- amino -acid enterotoxin with no subunit structure, which contains three disulfide bonds important for biologic activity. As shown in Figure 16-2, STa binds to an extracellular domain of guanylate cyclase, resulting in increased intracellular levels of cyclic guanosine monophosphate (cGMP), which ultimately leads to decreased absorption of sodium and increased chloride secretion.

In addition to *Vibrio cholerae*, occasional other bacteria, including *Klebsiella*, *Enterobacter*, *Morganella*, *Aeromonas*, *Plesiomonas*, *Campylobacter*, and *Salmonella* species, have been shown to elaborate LT-like toxins.<sup>5,89-94</sup> An STa-like peptide toxin, EAST-1, is produced by many EAEC and EHEC isolates and causes fluid secretion in a cGMP-dependent manner.<sup>95,96</sup>

### Enteropathogenic *E. coli*

Unlike in ETEC, secretory exotoxin elaboration does not play a role in the pathogenesis of EPEC. The basic pathogenic feature of these organisms is the attaching-and-effacing lesion, which is characterized by degeneration of the microvillus brush border, with cupping and pedestal formation of the plasma membrane at sites of bacterial attachment, noted histologically<sup>97</sup> (Fig. 16-3). Figure 16-4 depicts the four-stage

model of EPEC pathogenesis, proposed by Donnenberg and Kaper,<sup>98</sup> as well as the mechanism of its invasive capacity. Localized adherence is mediated by the bundle-forming pilus, which is primarily encoded by the *bfpA* gene. A chromosomal *dsbA* gene that encodes a periplasmic enzyme capable of disulfide bond catalysis also appears to be necessary at this step. Adherent bacteria then express a type III secretion system (TTSS) “needle complex,” which penetrates the host cell membrane and injects bacterial proteins, most notably Tir. After injection, Tir is tyrosine phosphorylated, leading to recruitment of cytoskeletal elements that form a tall pedestal upon which the bacterium sits. The *eae* gene product, intimin, sits in the bacterial cell wall and binds directly to Tir, helping to anchor the bacterium to the pedestal. A number of additional proteins secreted by the TTSS have been identified, some of which reside in the LEE (locus of enterocyte effacement), which was clearly identified as a virulence trait in EPEC strains in human volunteer studies.<sup>99</sup> Additional non-LEE TTSS effectors have been recently described, adding additional complexity to the question of how EPEC causes diarrhea.<sup>100,101</sup> Several of these effectors appear to modulate host signaling and are required for full pathogenicity in closely

**FIGURE 16-3** A, Three types of HEp-2 cell attachment: locally adherent enteropathogenic *E. coli* (EPEC, left), diffusely adherent *E. coli* (DAEC, center), and enteroaggregative *E. coli* (right). B, EPEC attachment and effacement on human enterocytes in a patient with diarrhea. (From Rothbaum R, McAdams AJ, Giannella R, et al: A clinicopathologic study of enterocyte-adherent *Escherichia coli*: A cause of protracted diarrhea in infants. *Gastroenterology* 83:441, 1982.)

**FIGURE 16-4** Four-stage model of EPEC (and EHEC) pathogenesis. Step 1: Bacteria contact the epithelial surface and adhere loosely via bundle-forming pili (BFP) and EspA projections. Step 2: Intimate attachment begins as bacteria inject Tir and other effectors via the type three secretion system (TTSS). Tir inserts into the host cell membrane and binds intimin on the bacterial surface. Meanwhile, host proteins are recruited to the cytoplasmic tail of Tir and begin cytoskeletal rearrangements. Step 3: Actin recruited to the contact point with the bacteria forms an elongated pedestal. TTSS effectors alter host cell physiology. Shown are Map, which damages mitochondria, and EspF, which causes apoptosis. Step 4: Pedestal formation and cell damage continue, leading to loss of membrane and mucosal barrier integrity. In addition, invasion of bacteria can occur at this stage. (Modified from Donnenberg MS, Kaper JB: Enteropathogenic *Escherichia coli*. Infect Immun 60:3953, 1992; and Tesh VL, O'Brien AD: Adherence and colonization mechanisms of enteropathogenic and enterohemorrhagic *Escherichia coli*. Microb Pathol 12:245, 1992.)

associated animal pathogens (*Citrobacter rodentium*, rabbit enteropathogenic *E. coli*). A list of known TTSS effectors of EPEC and other pathogenic proteins is given in Table 16-3. Although EPEC organisms do not cause keratoconjunctivitis in guinea pigs, a property classically associated with invasive *Shigella* and EIEC, invasion has been observed in clinical specimens, in vivo experimental models, and a variety of epithelial cell types in vitro.<sup>102–107</sup> Exactly how any of these epithelial cell changes lead to diarrhea has not been fully worked out. Incubation of EPEC with polarized epithelial monolayers results in decreased transepithelial resistance, possibly reflecting an increase in permeability that could contribute to diarrhea.<sup>108</sup> In addition, the loss of microvilli likely leads to malabsorption.<sup>109</sup>

The role of immune responses in EPEC infection is uncertain. The distinctively different age-specific attack rates may be explained by the development of immunity following colonization or infection with EPEC. Certain TTSS effector proteins, especially intimin and Tir, are highly immunogenic in mice.<sup>110</sup> Alternatively, the loss of age-specific receptors may account for the dramatic drop in EPEC infection in patients older than 6 months of age.<sup>111</sup> Several lines of evidence suggest that breast milk may provide passive immunity against EPEC infection. In addition to the association of EPEC infection with bottle feeding, secretory IgA to the EPEC adherence factor (EAF) and oligosaccharide fractions of human colostrum and breast milk have been shown to inhibit localized adhesion of EPEC to HEp-2 cells.<sup>112,113</sup>

### Enterohemorrhagic *E. coli*

At least two virulence traits, attaching-and-effacing ability and Shiga-like toxin elaboration, confer pathogenicity to EHEC organisms. Like EPEC, EHEC cause filamentous actin

accumulation at the site of attachment in association with “cup and pedestal” formation.<sup>114</sup> As in EPEC, this is achieved through the actions of genes on a chromosomal pathogenicity island analogous to the LEE. However, there are some differences between EPEC and EHEC pedestals; notably, EHEC Tir does not require tyrosine phosphorylation in order to initiate pedestal formation.<sup>115</sup>

What distinguishes EPEC from EHEC more obviously are the Shiga-like toxins (SLTs) of EHEC. These toxins, which are structurally and functionally similar to the Shiga toxin from *Shigella dysenteriae* I, are also referred to as verotoxins, reflecting their cytotoxicity for Vero cells. Thus, EHEC has been variably referred to in the literature as STEC and VTEC. Current convention is to label as EHEC only those organisms that have both attaching-and-effacing ability and express one or both SLTs.<sup>48</sup> At least two immunologically distinct SLTs, both with one A and five B subunits, have been described. The 70-kDa SLT-I is virtually identical to Shiga toxin and is neutralizable by antiserum against Shiga toxin. The smaller 60-kDa SLT-II is neutralized by antibodies to neither Shiga toxin nor SLT-I.<sup>116,117</sup>

Although SLTs alone are capable of stimulating bloody fluid accumulation and mucosal injury in multiple animal models,<sup>118,119</sup> SLT production does not appear to be requisite for developing diarrhea in EHEC infections.<sup>120</sup> In severe disease, particularly when bloody diarrhea is present, it is thought that SLTs gain systemic access and that they, particularly SLT-II, play a central role in the development of HUS. It is proposed that SLTs, which inhibit protein synthesis in a number of cell lines in vitro, do so in endothelial cells (Fig. 16-5), ultimately causing them to detach and expose platelets to the subendothelium, thus initiating coagulation.<sup>121,122</sup> The receptor for the SLT B subunit, globotriosyl ceramide or Gb3, is highly expressed in several of

**FIGURE 16-5** Shiga-like toxins (SLTs) I and II produced by enterohemorrhagic *E. coli* bind to globotriosyl ceramide (Gb<sub>3</sub>) via B subunits and undergo receptor-mediated endocytosis. The A subunit, after release into the cytoplasm, is proteolytically degraded to A<sub>1</sub> and A<sub>2</sub> fragments. The former binds to the 60S ribosome and cleaves an adenine residue at position 4324 in 28S ribosomal RNA, thereby halting protein synthesis and causing cell death. ATP, adenosine triphosphate.

the target organs of EHEC/HUS, including the colon, kidneys, and brain.<sup>123–126</sup> In addition, in rabbits SLT-I has been shown to induce a thrombotic microvascular angiopathy similar to that seen in humans with HUS.<sup>118</sup> Epidemiologic data suggest that SLT-II may be more important than SLT-I for progression of *E. coli* O157:H7 infection to HUS.<sup>53,127,128</sup>

The role of antibodies in protecting against EHEC infection or its complications remains unknown. Although the epidemiologic observation of increased rates of infection and complications in young children and the elderly may suggest a role for immunity in preventing infection, reports of recurrent hemorrhagic colitis and HUS associated with recurrent *E. coli* O157:H7 infections argue against a key role for protective immunity.<sup>59,129,130</sup> However, there is hope that a bovine vaccine raised to adherence factors of EHEC may prevent colonization with these organisms and thereby eliminate spread to humans.

### Enteroaggregative *E. coli*

Data from several volunteer studies demonstrate marked variability in EAEC pathogenicity in adults.<sup>65,66,131</sup> It is

possible that this category of *E. coli*, defined primarily by a phenotypic assay (stacked-brick HEp-2 cell adherence), includes subsets of *E. coli* with varied (or no) virulence traits. However, phylogenetic analysis suggests that there are three distinct subfamilies of EAEC with common traits, indicating that EAEC is not as heterogeneous a class of bacteria as was once thought. Moreover, there is clinical evidence that strains with a “typical” adherence pattern and strains that express the transcriptional regulator *aggR* and genes in its regulon are more likely to be pathogenic than atypical strains.<sup>38,132</sup>

There are a number of identified virulence traits in EAEC. The characteristic HEp-2 adherence is mediated by flexible bundle-forming fimbrial structures, aggregative adherence fimbriae (AAF), of which at least three distinct types exist. The AAF are encoded by two separate gene clusters on the 60-MDa AA plasmid.<sup>133</sup> Also encoded on the plasmid is Pet, a member of the serine protease autotransporter toxin family. Pet cleaves host cytoskeletal proteins and may be responsible for many of the cytotoxic effects of EAEC in vitro. An additional plasmid protein, dispersin, is expressed during EAEC infection, and serves to release AAF attachments to allow for bacterial dispersion.<sup>134</sup> Many EAEC isolates also encode a plasmid-borne enterotoxin, designated EAST-1, which bears significant homology with the enterotoxin domains of ST and guanylin.<sup>96</sup>

In addition to the plasmid virulence traits noted previously, EAEC strain 042 (the prototype pathogenic in volunteers) expresses several chromosomal virulence traits. One of these proteins, Pic, is a mucinase that likely contributes to the distinctive intestinal adherence of EAEC.<sup>135,136</sup> The opposite strand from Pic in the same location encodes a protein, ShET-1, that was first identified as an enterotoxin in *Shigella flexneri*.<sup>137</sup> Finally, EAEC 042 expresses a highly inflammatory flagellin, which causes IL-8 release from epithelial cells in vitro and appears to be responsible for most if not all of the inflammatory response to EAEC.<sup>138</sup>

### Diffusely Adherent *E. coli*

Less is known about DAEC pathogenesis than about other *E. coli* pathotypes. The diffusely adherent phenotype can be mediated by either fimbrial (F1845) or afimbrial (AIDA-1) adhesins.<sup>139,140</sup> These adhesins are homologous to Afa/Dr adhesins found on many uropathogenic *E. coli*, and bind to decay accelerating factor (CD55), leading to clustering of this protein in the cell membrane and unique ultrastructural changes.<sup>141–144</sup> Toxic effects include loss of tight junction integrity<sup>145</sup> and basolateral cytokine release.<sup>146</sup>

### Enteroinvasive *E. coli*

Like *Shigella*, EIEC penetrates and multiplies within colonic epithelial cells, eventually causing cell death and the exuberant host inflammation responsible for much of the dysenteric clinical syndrome. A large 140-MDa plasmid that has extensive homology with the invasion plasmid of *Shigella* species mediates these virulence properties.<sup>147</sup> The invasion plasmid encodes a TTSS that injects effectors IpaA, B, and C and IpgD, which recruit epithelial cell signaling to create cytoskeletal rearrangements that permit entry of the bacterium

(reviewed in Kaper and colleagues<sup>48</sup>). An additional plasmid-encoded protein, IcsA, localizes to one pole of the bacterial outer membrane where it binds neural Wiskott–Aldrich syndrome protein (N-WASP), leading to actin condensation. This polar actin condensation pushes the bacterium through the cytoplasm and ultimately into adjacent cells, leading to horizontal spread through the epithelium.<sup>148,149</sup> Other virulence traits expressed by some EIEC isolates include plasmid-encoded enterotoxins, which may explain the watery diarrhea often seen in early stages of EIEC infection.<sup>150,151</sup> It was also recently shown that EIEC can trigger inflammation in intestinal epithelial cells by activating the host protein Nod1.<sup>152</sup>

## DIAGNOSIS

Because of the ubiquity of *E. coli* in fecal material, definitive diagnosis of enteric infections with enterovirulent *E. coli* often involves sophisticated techniques to detect the virulence traits themselves, many of which are beyond the scope of most clinical diagnostic laboratories. Of the enterovirulent *E. coli*, EHEC is most easily identified because of the dominant prevalence of serotype O157:H7. Because *E. coli* O157:H7, unlike most *E. coli*, does not ferment sorbitol, sorbitol-MacConkey agar is used as a screening medium. Presumptive diagnosis of *E. coli* O157:H7 infection can be made when sorbitol-negative (clear) *E. coli* isolates are shown to agglutinate in the presence of *E. coli* O157 antiserum.<sup>153</sup> However, non-O157 EHEC isolates, which can cause human disease, will be missed by this method. Newer immunologic techniques that detect SLT-I and SLT-II in stool are therefore in widespread use.<sup>154</sup> Screening for EHEC by one of these methods is recommended for all bloody stool samples received in diagnostic laboratories.<sup>155</sup>

The enteroadherent *E. coli* types (EPEC, EAEC, and DAEC) are classically identified by the HEP-2 cell adherence assay in which HEP-2 cells are incubated with *E. coli* isolates, washed, stained, and then examined microscopically for adherence patterns. EPEC attaches in focal aggregates (local adherence), EAEC adheres to both HEP-2 cells and glass in a stacked-brick pattern, and as suggested by the name, DAEC adheres in a diffuse pattern to cells (but not glass). Although a number of technical variations in the HEP-2 cell adherence assay have been described, it appears that the so-called CVD (Center for Vaccine Development, University of Maryland) method or a modification of the UTH (University of Texas, Houston) method to include a 2- to 4-hour postwash incubation is best able to distinguish all three patterns.<sup>156,157</sup> A simpler version using prefixed HEP-2 cells was shown to be 92% sensitive for detection of EAEC.<sup>158</sup> EAEC may also be sensitively identified by biofilm formation when grown in rich media in the absence of cells, although the specificity appears lower than with HEP-2 cells.<sup>159</sup>

EPEC is distinguished by establishing the presence of characteristic enterotoxins or the genes which encode them. LT or ST can be identified using tissue culture techniques (such as the Chinese hamster ovary cell elongation assay for LT)<sup>160</sup> or cyclic GMP elevations in T84 cells for ST.<sup>88</sup> Less cumbersome techniques include several commercially available immunoassays.<sup>161,162</sup> Genetic techniques using DNA probes or PCR have also been used.<sup>163–167</sup>

DNA tests for EPEC, EAEC, and DAEC have also been used with varying degrees of success. The most useful of these for EPEC are the EAF and *eaeA* probes, which detect the adherence plasmid and LEE pathogenicity island, respectively. The AA probe for EAEC (which recognizes a portion of the AA plasmid)<sup>168</sup> has been shown to be highly sensitive and specific in some studies, but it is clear that probe-negative strains predominate in clinical disease in some areas of the world. Newer probes targeting *aggR*, *pic/set*, and *aap* appear promising, but larger studies are pending.<sup>169,170</sup> Probes for the Afa/Dra adhesins of DAEC are also being studied.

Classically, EIEC was identified using the animal model of invasion, such as the Séreny test in which invasion is demonstrated in the conjunctiva of guinea pigs.<sup>171</sup> More recently, molecular techniques using DNA probes and PCR have shown promise as highly sensitive and specific alternatives to the more classic diagnostic methods.<sup>172,173</sup>

## TREATMENT

### Rehydration

As with all diarrheal diseases, replacement of lost fluid and electrolytes is the cornerstone of therapy. This is best accomplished with the oral rehydration formulation recommended by the World Health Organization (Table 16-4). The formulation is based on the physiologic observation that intestinal absorption of sodium is coupled to that of glucose, and that addition of glucose to sodium-containing solutions drives sodium absorption even in the face of ongoing intestinal secretion. Simple and inexpensive, oral rehydration therapy has been credited with saving up to 1 million lives per year.<sup>174</sup> Oral rehydration is preferred over intravenous therapy for several reasons: It is more physiologic (with an intact thirst mechanism, overhydration is avoided), less expensive, less painful, safer (no risk of intravenous catheter infections), and much easier to administer in developing countries.

Successful use of oral rehydration therapy begins with a careful assessment of the patient's hydration status. Guidelines for assessing dehydration in children are listed in Table 16-5. In addition, assessment of capillary refill time,<sup>175</sup> urine output, and urine specific gravity may be useful measures of dehydration and response to rehydration therapy.<sup>176</sup> Oral rehydration is recommended for those with mild to moderate dehydration. When severe dehydration (10% or

**Table 16-4 Oral Rehydration Formulas**

WHO Formula		Home Recipe	
Ingredient	Amount*	Ingredient	Amount*
NaCl	3.5 g	Table salt	1/2–3/4 tsp
NaHCO <sub>3</sub>	2.5 g	Baking soda	1/2 tsp
KCl	1.5 g	Orange juice	1 cup
Glucose	20 g	Table sugar†	4 level tsp

WHO, World Health Organization.

\*Per liter (1.05 qt) of clean water.

†Food-based oral rehydration formulations, prepared by replacing table sugar with 50 to 60 g of cereal flour or 200 g of mashed boiled potato, may help to reduce fluid output.

**Table 16-5** Evaluation of Dehydration in Patients with Diarrhea

Variable	Mild (3%–5% Body Weight)	Moderate (6%–9% Body Weight)	Severe (≥10% Body Weight)
Blood pressure	Normal	Normal	Normal to reduced
Heart rate	Normal	Increased	Increased*
Quality of pulses	Normal	Normal or slightly decreased	Moderately decreased
Skin turgor†	Normal	Decreased	Decreased
Mucous membranes	Slightly dry	Dry	Dry
Eyes	Normal	Sunken orbits	Deeply sunken orbits
Tears	Present	Absent	Absent
Extremities	Warm, normal capillary refill	Delayed capillary refill	Cool, mottled
Mental status	Normal	Normal to listless	Normal to lethargic or comatose
Urine output	Slightly decreased	Moderately decreased	Severely decreased to anuric

\*Bradycardia may develop in severe cases.

†May not be reliable in the presence of severe malnutrition.

Adapted from Bern C, Martines J, deZoysa I, et al: The magnitude of the global problem of diarrheal disease: A ten-year update. Bull World Health Organ 70:705, 1992.

more of body weight) is present, intravenous therapy with normal saline or Ringer's lactate is recommended, and serum electrolytes should be measured and corrected if oral therapy cannot be given first. As soon as dehydration has been corrected, age-appropriate refeeding can further reduce stool output, decrease the duration of diarrhea, and improve nutritional values.<sup>176–178</sup>

### Antimicrobial Therapy

In placebo-controlled trials published in the early 1980s, tetracycline, trimethoprim-sulfamethoxazole, and trimethoprim alone were all shown to decrease the duration of diarrhea in either naturally acquired ETEC infection or in volunteers experimentally infected with the organism.<sup>179,180</sup> Since then, a number of studies of *E. coli* isolates in developing countries have reported increased resistance to multiple antimicrobials, including ampicillin and trimethoprim-sulfamethoxazole.<sup>181–186</sup> Fortunately, the vast majority of *E. coli* isolates remain sensitive to fluoroquinolones,<sup>183–185,187</sup> and multiple studies have demonstrated the efficacy of these agents in the treatment of traveler's diarrhea, including the subgroups infected with ETEC and EAEC.<sup>37,187–190</sup> Abbreviated courses of quinolone therapy for 3 days<sup>187,191</sup> or even single dose<sup>188</sup> have documented efficacy in patients with traveler's diarrhea. Rarely, ciprofloxacin resistance has emerged in multidrug-resistant *E. coli* isolates from travelers treated with ciprofloxacin.<sup>191</sup> Effective therapy for EAEC-associated traveler's diarrhea using the nonabsorbable antibiotic rifamixin has also been demonstrated in a small clinical trial.<sup>192</sup> Ciprofloxacin was also effective in curing EAEC diarrhea in a small group of HIV-infected patients.<sup>40</sup> Specific therapy for DAEC has not been studied. Several reports suggest the efficacy of antibiotics in managing EPEC infections,<sup>97,193,194</sup> although the only controlled trial specifically addressing EPEC infections was with 49 Ethiopian children in whom serotype O111:B4 predominated.<sup>194</sup> In this series, complete resolution of diarrhea was seen within 3 days in 73% of cases receiving trimethoprim-sulfamethoxazole (and in 76% in those receiving mecillinam) vs. 7% in controls, and bacterio-

logic cure was confirmed in 53% of those receiving antibiotics vs. none in the control group. In addition to rehydration therapy and antibiotics, parenteral nutrition supplementation may be helpful in the severely malnourished patient with EPEC infection.<sup>97</sup> In multiple regions worldwide, antimicrobial resistance among EPEC isolates is emerging<sup>195–197</sup>; if feasible, antimicrobial selection should be guided by susceptibility testing.

The role of antimicrobial treatment in EHEC disease remains uncertain. Although most *E. coli* O157:H7 is susceptible in vitro to antibiotics such as ampicillin, carbenicillin, gentamicin, cephalothin, chloramphenicol, quinolones, trimethoprim, and trimethoprim-sulfamethoxazole,<sup>78,198–200</sup> exposure of the organism to sublethal concentrations of trimethoprim-sulfamethoxazole, ciprofloxacin, and tetracycline has been reported to increase SLT release.<sup>201</sup> Of note, ciprofloxacin also stimulates increased release of endotoxin from *E. coli*,<sup>202,203</sup> which can result in significant cytokine release from whole blood and human peripheral blood monocytes.<sup>204,205</sup> There is limited clinical evidence that antibiotics may be harmful in EHEC infection, including a prospective but nonrandomized study,<sup>206</sup> suggesting an association between antibiotic use and progression to HUS. Among retrospective studies from several outbreaks, antibiotics did not appear to influence the duration of symptoms.<sup>78,207</sup> In one retrospective case series of 20 patients with *E. coli* O157:H7 infection, treatment with trimethoprim-sulfamethoxazole was significantly associated with the development of HUS.<sup>79</sup> However, other studies report an association of appropriate antimicrobial therapy for more than 24 hours with lack of progression to HUS.<sup>81</sup> In the only prospective randomized therapeutic trial in EHEC diarrhea, the duration of symptoms was not significantly reduced by trimethoprim-sulfamethoxazole, although treatment was begun relatively late in the illness.<sup>208</sup> In addition, the preceding prospective study found a trend toward the development of HUS in the group not receiving antibiotics, although this did not reach statistical significance.<sup>208</sup> A recent meta-analysis of nine studies (six retrospective and three prospective) did not show a higher risk of HUS following antibiotic administration.<sup>209</sup>

Bacillary dysentery associated with EIEC typically responds to appropriate antimicrobials targeting shigellosis. As with *Shigella* species, antibiotic susceptibility patterns vary geographically, and antimicrobials such as ampicillin and trimethoprim-sulfamethoxazole may not be effective against EIEC. Resistance to third-generation cephalosporins and quinolones, including nalidixic acid, is less common.<sup>210,211</sup>

## Other Therapies

### Bismuth Subsalicylate

In addition to oral rehydration therapy and specific antimicrobial therapy, a number of other agents may help to treat enteric *E. coli* infections. Bismuth subsalicylate has been used ever since the early 1900s as an antidiarrheal agent, and several studies have validated its efficacy in treating diarrhea caused chiefly by enterovirulent *E. coli*.<sup>212</sup> Its efficacy in preventing and treating ETEC infections has been shown in volunteers fed ETEC, as well as in field trials.<sup>213,214</sup> In addition, in a recent randomized placebo-controlled trial in which the most commonly isolated potential pathogen was *E. coli* with EPEC serotypes, bismuth subsalicylate effected a significant reduction in duration of diarrhea, duration of hospitalization, and stool output in infants and young children with acute watery diarrhea.<sup>215</sup> Nonetheless, antidiarrheal drugs including bismuth subsalicylate are generally not recommended in treating infants with acute diarrhea caused by any pathogen.<sup>176</sup>

### Antimotility Agents

Loperamide shortens the time to the last unformed stool in traveler's diarrhea and may offer some modest benefit in patients infected with ETEC during the first 24 hours of combination therapy with ciprofloxacin; however, antimotility agents may mask fluid losses and should not be used in children.<sup>216–218</sup> The safety of antimotility agents in EIEC infections is uncertain. Murphy and associates<sup>219</sup> reported no adverse effects in 42 adult patients with dysentery who received loperamide in combination with ciprofloxacin and, compared with 46 receiving ciprofloxacin alone, this regimen resulted in fewer unformed stools and a shorter duration of diarrhea.<sup>219</sup> Nonetheless, the modest symptomatic improvement seen with antimotility agents in this disease must be weighed against reports of adverse outcomes associated with their use in inflammatory diarrheal illnesses.<sup>220,221</sup> Given reports associating antimotility agents with the development of HUS,<sup>81,222,223</sup> and increased risk of central nervous system manifestations in HUS<sup>224</sup> in EHEC infections, they should clearly be avoided in patients suspected of having hemorrhagic colitis.

### Probiotics

There has been significant enthusiasm for the use of live bacterial preparations as “natural” remedies for gastrointestinal illness. While live-culture yogurt has antibacterial activity in vitro,<sup>225</sup> it had no significant clinical effect in rabbit EPEC infection in one study.<sup>226</sup> Yogurt was shown to be no more effective than milk in treating acute diarrhea in malnourished children.<sup>227</sup> Newer probiotic preparations containing defined organisms have shown more promise. One such organism,

*Lactobacillus* GG, shortens the duration of acute diarrhea in children with rotavirus infection but not bacterial diarrhea.<sup>228–230</sup> In one trial, prophylactic administration of *Lactobacillus* GG to undernourished children in Peru did decrease the incidence of diarrheal episodes (5.21 episodes/child/year vs. 6.02 for placebo;  $p < 0.05$ ).<sup>231</sup> *Lactobacillus* GG was also shown to prevent traveler's diarrhea in two randomized, blinded, placebo-controlled studies, although the effect was limited to travelers to particular areas (Turkey, North Africa).<sup>232,233</sup> In summary, there is currently no evidence to support the routine use of any probiotic preparation in the prevention or treatment of *E. coli* enteric infection, although this remains an area of active investigation.

## PREVENTION AND CONTROL

As with the vast majority of pathogens causing diarrheal illness, proper sanitation and hygiene aimed at diminishing the risk of fecal-oral transmission is important for the prevention of enteric *E. coli* infections. Culturally sensitive education on the use of soap and handwashing after defecation and before eating or preparing foods and improvements in the disposal of human waste are the simplest and, perhaps overall, the most effective means of preventing disease caused by most enteric *E. coli*.<sup>234–238</sup> Numerous studies have demonstrated the protective benefits of breastfeeding in preventing diarrheal diseases, including those associated with ETEC and EPEC.<sup>21,239,240</sup> Not only does breastfeeding diminish the risk of fecal-oral exposure from exposure to weaning foods, but breast milk likely affords immunologic protection<sup>241</sup> and may contribute oligosaccharides and other substances which interfere with attachment of *E. coli* to intestinal epithelium.<sup>112,113</sup> Programs which address deficiencies in micronutrients such as vitamin A and zinc have also been shown to improve the severity of diarrhea in developing regions.<sup>242–245</sup>

Those traveling to the tropics should be advised to eat only those foods that are thoroughly cooked and served piping hot, or fresh fruits that can be peeled. In general, chemoprophylaxis for traveler's diarrhea is not recommended. People who are at high risk of complications from traveler's diarrhea, such as those with diabetes, inflammatory bowel disease, advanced AIDS, or those on immunosuppressive drugs, should be warned that agents such as *Cryptosporidium* are not prevented by antibiotics and may cause far worse disease than ETEC or EAEC. Moreover, the increasing antibiotic resistance of certain pathogens (e.g., *Campylobacter* in Thailand) makes chemoprophylaxis less attractive.

Given the striking association of EHEC infection with bovine sources in developed countries, preventive efforts have focused primarily on inspection of food products and new microbiologic quality standards.<sup>246</sup> Increased industrialization of food supplies in developing countries and greater sharing of food sources globally multiply the potential for outbreaks with enteric *E. coli* such as EHEC and other gastrointestinal pathogens. Stricter governmental and industrial standards may help prevent widespread point-source outbreaks.

Vaccine development targeting *E. coli* enteric infections is an active field of study. Several trials of a combined oral inactivated cholera/CT-B subunit vaccine to prevent traveler's diarrhea due to ETEC have had promising results.<sup>247–251</sup> This vaccine is available in Europe and Australia and was recently

marketed in Canada (Dukoral, Aventis Pasteur) but is not available in the United States. Additional human vaccines against ETEC and EHEC are under development. In addition, a vaccine to prevent EHEC colonization of beef cattle is undergoing trials.

# Typhoid Fever\*

JUDITH E. EPSTEIN  
STEPHEN L. HOFFMAN

## INTRODUCTION

Typhoid fever is an acute systemic illness caused by infection with *Salmonella enterica* subspecies *enterica* serotype Typhi. It is characterized by (1) prolonged fever, (2) sustained bacteremia without endothelial or endocardial involvement, and (3) bacterial invasion of and multiplication within the mononuclear phagocytic cells of the liver, spleen, lymph nodes, and Peyer's patches. Paratyphoid fever is a pathologically and clinically similar, but generally milder, illness that is caused by many serotypes of the genus *Salmonella* but most commonly by *Salmonella* serotypes Paratyphi A, Schottmuelleri, and Hirschfeldii. Enteric fever refers to either typhoid or paratyphoid fever.

Although Hippocrates may have written about typhoid fever, it was not until the early 19th century that French workers described the clinical and pathologic features of *dothiéntérite* (boil of the intestine), which was endemic in Paris. In 1829, Pierre Louis first called it *typhoïde* meaning "typhus-like," but he did not distinguish between the typhoid of Paris and the typhus that was then common in Great Britain. Thus both typhoid and typhus take their names from the Greek *typhos*, which means "smoke" and refers to the apathy and confusion associated with fever that are such prominent features of the fully developed clinical syndromes and also refers to the belief that the diseases had their origin in miasmatic vapors. In 1837, William Wood Gerhard, a former student of Louis working in Philadelphia, clearly differentiated typhoid from typhus fever, both clinically and pathologically. He wrote: "The anatomical characters of these varieties of fevers are peculiar to themselves and it is [as] impossible to substitute the lesion of the follicles of the small intestine observed in typhoid fever from [for] the pathological phenomena of typhus as it is by other treatment or means to transform the eruption of measles into the pustules of smallpox."

In 1880, Eberth described *Bacillus typhosus* in histologic sections of mesenteric lymph nodes and the spleen. Four years later, Gaffky successfully cultured *Salmonella* Typhi and stressed that the infection was waterborne and not airborne. In 1896, Achard and Bensaude isolated *S. Paratyphi* B and

first used the term *paratyphoid fever*. In the same year, Widal described the eponymous reaction, and Wright from England and Pfeiffer from Germany introduced the first vaccination against typhoid.

Until 1948, there were no other major advances in the prevention, diagnosis, or treatment of typhoid fever. Modifications of the first inactivated whole-cell vaccines were used for prevention, Widal's test and culture were used for diagnosis, and patient management was supportive, the outcome being highly dependent on the quality of nursing care. In 1948, Woodward and colleagues,<sup>1</sup> who were working in Malaysia to determine if chloramphenicol was effective in treating scrub typhus, found that one of their suspected scrub typhus patients had typhoid fever and that chloramphenicol rapidly cleared the bacteremia and markedly shortened the duration of the illness. Until the emergence of resistance, chloramphenicol was the antimicrobial agent of choice for treating both typhoid and paratyphoid fever. In the 1970s and 1980s, live oral attenuated<sup>2-4</sup> and Vi capsular polysaccharide<sup>5,6</sup> *S. Typhi* vaccines were developed and shown to be effective in large field trials. By the mid 1990s, these vaccines had replaced whole-cell vaccines in adults and children older than 2 years of age. More recently, a Vi capsular polysaccharide-conjugate vaccine has been shown to be even more effective than the previous vaccines<sup>7,8</sup> and it is expected that it will replace the other vaccines in the coming years. Fortunately, as drug resistance has emerged to existing antibiotics, new drugs such as fluoroquinolones and third-generation cephalosporins have proven successful in the treatment of typhoid fever. Nevertheless, there is concern that drug resistance may outpace the effectiveness of available drugs. It is hoped the availability of the genomic sequence of *S. Typhi*<sup>9</sup> will provide the foundation for new methods of prevention, diagnosis, and treatment of typhoid fever.

## AGENT

*Salmonella* is the most complex genus in the family Enterobacteriaceae, with more than 2400 serotypes currently listed in the Kauffman-White scheme. Because multiple nomenclature systems are used, classification of the organism can be confusing. Previously, salmonellae were classified as having three distinct "species": *S. choleraesuis*, *S. typhi*, and *S. enteritidis*. Most of the described serotypes belonged to the species *S. enteritidis*. Salmonellae were further grouped (A, B, C, etc.) based on somatic O antigen and further divided into serotypes (1, 2, 3, etc.) based on flagellar H antigens.<sup>10</sup>

All *Salmonella* and *Arizona* isolates are now considered to be a single species (*Salmonella enterica*), separated into seven distinct subgroups: I, II, IIIa, IIIb, and IV through VI. Subgroup I contains most of the *Salmonella* serotypes responsible for human disease. Based on this new schema, the complete name for all isolates is designated as, for example, *Salmonella enterica* subspecies *enterica* serotype Typhi. However, due to wide clinical use and familiarity, it is still appropriate to address them as, for example, *Salmonella* Typhi, as long as it is understood that these organisms are a serotype of the species *Salmonella enterica* and not a distinct species. In this chapter, the name *S. Typhi* will be used throughout. All salmonellae grow on simple media; however, specimens are usually cultured on a selective medium, such as *Salmonella-Shigella*

\*All material in this chapter is in the public domain, with the exception of any borrowed figures or tables. The opinions or assertions herein are those of the authors and are not to be construed as official or as reflecting the views of the U.S. Navy or the naval service at large.

\*Except for *S. Typhi*, most *Salmonella* serotypes cannot be distinguished by biochemical reactions.

agar, to avoid the overgrowth of salmonella by other enteric bacteria.

The various salmonellae can now be differentiated by polymerase chain reaction (PCR), using nested fliC (flagellin gene) and Vi-associated primers. Until recently, differentiation depended on the use of biochemical and serologic reactions, that is, agglutination patterns with O, H, and Vi homologous antisera. The biochemical differences between *S. Typhi*, *S. Paratyphi A*, and *S. Schottmuelleri* (*Paratyphi B*) are summarized in Table 17-1. The serologic classification using the Kauffman-White agglutination scheme of antigenic analysis is summarized in Table 17-2. Among the salmonellae, only *S. Typhi* and *S. Hirschfeldii* (*Paratyphi C*) have the important K antigen called the Vi antigen. Vi stands for virulence, and *S. Typhi* with this antigen are thought to be more virulent than those without, possibly because the envelope protects the somatic O antigen from bactericidal antibody (Fig. 17-1).

*S. Typhi*, the etiologic organism of typhoid fever, is similar to other salmonellae in that it is a gram-negative, flagellate, nonencapsulated, nonsporulating, facultative anaerobic bacillus that ferments glucose, reduces nitrate to nitrite, synthesizes peritrichous flagella when motile, has a somatic (O) antigen (oligosaccharide), a flagellar (H) antigen (protein), an envelope (K) antigen (polysaccharide), and a lipopolysaccharide macromolecular complex called endotoxin that forms the outer portion of the cell wall (see Fig. 17-1). The endotoxin is composed of three layers: an outer (O, oligosaccharide), middle (R, core), and basal (lipid A layer). *S. Typhi* is also capable of developing R plasmid-transmitted antimicrobial resistance.

## GENOME

In 2001, the DNA sequence of the genome of a multiple-drug-resistant *S. Typhi* isolate, CT18, which was originally

isolated from a child with typhoid fever in the Mekong Delta region of Vietnam, was reported.<sup>9</sup> The genome of this isolate is 4,809,037 base pairs in length and is predicted to encode approximately 4600 genes. It has large regions of DNA with a high degree of conservation between species. For example, the genomes of *S. Typhi* CT18, *S. enterica* serotype Typhimurium LT2,<sup>11</sup> and *Escherichia coli*<sup>12</sup> are essentially colinear with approximately 80% of genes shared. Besides the conservation in terms of gene repertoire, the genes in the core region of the *S. Typhi* genome also demonstrate a conserved order on the chromosome between enteric bacterial species.

The *S. Typhi* CT18 genome also contains *S. Typhi*-specific regions, comprised of single genes or groups of gene clusters with as many as 100 genes per cluster, believed to be of relatively recent acquisition. These include at least 10 clusters of genes known as salmonella pathogenicity islands (SPI), which are thought to be involved in invasion and survival inside host cells, as well as smaller gene blocks thought to be involved in pathogenicity.

The *S. Typhi* genome contains more than 200 pseudogenes, which are DNA sequences that encode genelike sequences that have been inactivated. The inactivation is frequently the result of a single point mutation or frame-shift, suggesting that the inactivation occurred relatively recently. About three-quarters of the pseudogenes of *S. Typhi* are present as active genes in *S. Typhimurium*,<sup>13</sup> which has a wider host range. Since it is thought that these genes are involved in pathogenesis, immune recognition, and host range, their inactivation in *S. Typhi* provides a potential explanation for why *S. Typhi* is restricted to humans.<sup>13</sup>

The *S. Typhi* CT18 genome contains two plasmids, pHCM1 and pHCM2 (106.5 kb). pHCM1 is 218 kb and encodes resistance to chloramphenicol, ampicillin, trimethoprim, sulfonamides, and streptomycin. pHCM2 is 106.5 kb in length

**Table 17-2 Antigenic Analysis by the Kauffman-White Scheme of the Organisms Causing Typhoid and Paratyphoid Fever\***

<i>Salmonella</i> Serotype	O Antigen Group	O Antigens	<i>H</i> Antigens		K Antigens

<i>S. Choleraesuis</i>	C <sub>2</sub>	6,7	c <sup>†</sup>	1,5	—

\*As noted in the text, this classification scheme is no longer used. It is included here for historical comparison.

<sup>†</sup>May not be present in all strains.

**FIGURE 17-1** A schematic diagram of a single *Salmonella typhi* cell showing the locations of the H (flagellar), O (somatic), and Vi (K envelope) antigens. (From Sonnenwirth AC: In Davis BD et al [eds]: Microbiology, 2nd ed. New York, Harper & Row, 1973.)

and, although it bears resemblance to the pMT1 virulence-associated plasmid of *Yersinia pestis*, its phenotype is unknown.

It is hoped that the information gleaned from the sequencing of the *S. Typhi* genome will lead to a better understanding of the epidemiology of typhoid fever and to new diagnostic and therapeutic approaches. It has been suggested that the data also support the case for global eradication. Sequencing of selected pseudogene mutations from different *S. Typhi* isolates has demonstrated the presence of identical mutations,<sup>13</sup> suggesting that *S. Typhi* emerged only once, likely under distinct environmental conditions. Thus, if *S. Typhi* could be eliminated through a combination of increased immunization, better diagnosis and treatment, and improved

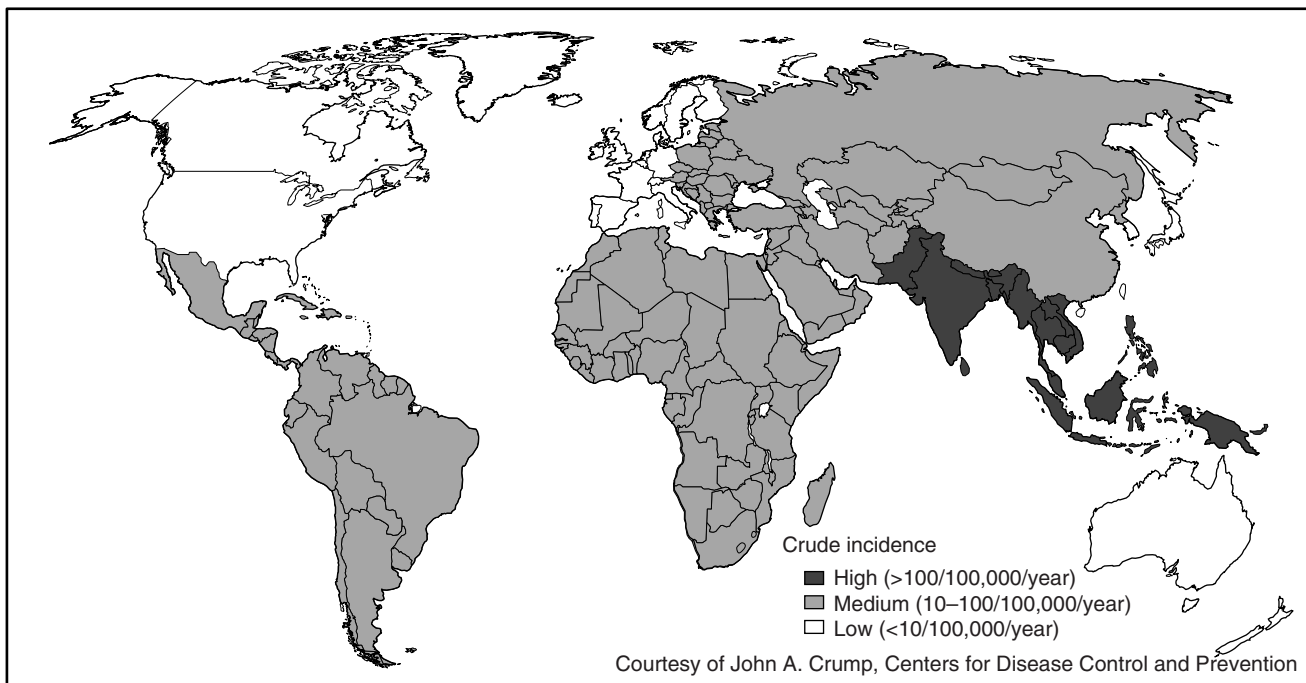

public health measures such as sanitation, it would be very unlikely to emerge again from other *S. enterica*.

## EPIDEMIOLOGY

### Distribution and Incidence

Patients with typhoid and paratyphoid fever may be encountered in all parts of the world but are now primarily found in those countries of the developing world where sanitary conditions are poor.<sup>14</sup> In the Spanish-American War, one-fifth of the U.S. troops developed typhoid fever, and over 1500 died of typhoid. In the Boer War, the British Army lost more men to typhoid (8225 deaths) than it did to wounds (7582 deaths). When Sir William Osler published his first textbook of medicine in 1892, the first chapter was on typhoid, and in 1909 Osler estimated that there were 500,000 cases per year in the United States and 35,000 to 40,000 deaths caused by typhoid.<sup>15</sup> The 1900s saw a dramatic decrease in the annual incidence of typhoid fever both in the United States and in most European countries. From 1973 until 2002, yearly typhoid fever cases in the United States ranged from a high of 680 cases in 1973 to a low of 321 cases in 2002.<sup>16</sup>

Although no longer a major problem in the developed world, many consider typhoid to be one of the most important and underreported diseases in the developing world. The underreporting is due to the fact that a positive blood culture is often required for diagnosis, and many patients with typhoid are treated where there are no bacteriology facilities. Annual incidence rates ranging from 198 per 100,000 (Vietnam) to 980 per 100,000 (India) have been documented within the past 5 years.<sup>17,18</sup> Similar incidence rates have been documented in Chile, Nepal, South Africa, and Indonesia in the past 15 years. Estimates of the incidence of

typhoid fever range from 16 million to 33 million new cases per year, with 216,000 to 600,000 deaths annually.<sup>19,20</sup> The majority of these cases are in Southeast Asia. In some areas it has been estimated that typhoid fever is responsible for 2% to 5% of all deaths.<sup>14</sup> Epidemics occur in the tropics and subtropics, but the majority of cases are reported in areas where typhoid fever is endemic. In these locations, there are so many sick or recovering people that chronic carriers may be less important in transmission than they are in the industrialized world. The incidence is frequently seasonal, with a peak in the hot, dry months of the year when the concentration of organisms in water is increased, not diluted by rains. In some areas the incidence is reported to peak during the rainy season when flooding apparently breaks down the systems that separate sewage from drinking water.

In areas where typhoid fever is endemic, it is likely that more than 95% of patients are treated as outpatients by local physicians. Thus, hospital-based incidence figures may underestimate the actual incidence by 15 to 25 times. In most areas of the developing world, the reported incidence of typhoid fever is at least two to three times that of paratyphoid fever, except during epidemics and in infants.

Since the introduction of antibiotics (chloramphenicol) in 1948 for the treatment of typhoid fever, in general the overall hospital case-fatality rates for typhoid fever have been less than 1%. However, there have been numerous reports of much higher hospital case-fatality rates.<sup>21</sup> Since typhoid frequently kills young adults, many of whom have recently finished school, entered the workforce, and become parents, the economic and social impact of typhoid on the family and society is often dramatic.

In industrialized nations with good sewage and water supply systems, most cases of typhoid fever are sporadic and are either imported or can be traced to contact with a chronic carrier. The majority of U.S. cases are acquired outside of the country, most commonly in travelers to Mexico and the Indian subcontinent.<sup>22</sup>

In the developed world, intermittent epidemics are generally attributed to a common-source exposure. In 1964, in Aberdeen, Scotland, 507 cases of typhoid fever occurred that were traced to ingestion of canned corned beef from Argentina. The leaky cans had been cooled in sewage-contaminated river water after canning. In 1973, there were 225 cases of typhoid fever in a migrant farm labor camp in Dade County, Florida.<sup>23</sup> The laborers were infected by drinking from the camp water supply system, which had a defective chlorinator and probably had been contaminated by a mentally retarded girl who acquired the infection from a chronic carrier who lived next door to her. In 1981, 78 cases of typhoid fever occurred in San Antonio, Texas. They were traced to a tortilla shop where one employee had *S. Typhi* in his stool.<sup>24,25</sup> In 1986, 10 cases of typhoid fever were acquired in a fast-food restaurant in Silver Spring, Maryland. They were traced to a shrimp salad prepared by an 18-year-old asymptomatic carrier who worked in the restaurant.<sup>26</sup> Another large typhoid fever outbreak occurred in 1989 at a resort hotel in Sullivan County, New York, where there were 45 confirmed, 24 probable, and 1 secondary typhoid fever cases. Twenty-one persons were hospitalized and two had bowel perforation. This outbreak was unusual in that contaminated orange juice was implicated as the vehicle

of transmission. The source of this outbreak may have been a kitchen worker from Central America who could not be located for testing and culturing.<sup>27</sup> In 1990, 17 cases of confirmed or probable typhoid fever occurred at a family gathering in Skagit County, Washington. They were traced to a food handler who was a chronic *S. Typhi* carrier.<sup>28</sup> An outbreak occurred in France in 1997 related to ingestion of contaminated pork.<sup>29</sup>

Although the incidence of outbreaks in the United States continue to decrease (from 1.85/year during 1960–1979 to 0.85/year during 1980–1999),<sup>30</sup> they continue to occur. Between 1960 and 1999, there were 60 outbreaks of typhoid fever in the United States, with primary exposure occurring in the United States in 54 of the outbreaks, accounting for 957 cases (median of 10 cases per outbreak) and 4 deaths<sup>30</sup>; 26 of the 60 outbreaks were foodborne.

### Antimicrobial Resistance

*S. Typhi* resistant to chloramphenicol was first reported in England in 1950,<sup>31</sup> 2 years after this antibiotic was first reported as successful in the treatment of typhoid fever.<sup>1</sup> Outbreaks of chloramphenicol-resistant *S. Typhi* occurred with an increasing incidence in the developing world from the early 1970s to the mid-1980s.<sup>32</sup> In the late 1980s and early 1990s, *S. Typhi* strains with plasmid-encoded resistance to chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole were detected in Asia and northeast Africa.<sup>33,34</sup> Infections with multidrug-resistant strains have been shown to be associated with higher bacterial blood counts, slower responses to treatment, increased number of complications, and a higher case-fatality than infection with strains of *S. Typhi* which are fully susceptible.<sup>32,35,36</sup> In a prospective study conducted in Vietnam from 1993–1994, over 70% of the *S. Typhi* strains isolated were multidrug resistant and 4% were resistant to nalidixic acid.<sup>37</sup> Fluoroquinolones and third-generation cephalosporins emerged in the 1990s as effective agents for treatment of most cases of typhoid fever with organisms resistant to standard antimicrobials.

*S. Typhi* strains with decreased susceptibility to fluoroquinolones, characterized by resistance to nalidixic acid, have been detected in Central, South, and Southeast Asia, as well as in the United Kingdom.<sup>38,39</sup> In 1997, an outbreak in Tajikistan with such a strain resulted in illness in 8000 people and 150 deaths.<sup>40</sup> In 1998, 76% of *S. Typhi* strains in one Vietnam study were reported to be nalidixic acid resistant.<sup>41</sup> In the United Kingdom, strains of *S. Typhi* with decreased susceptibility to ciprofloxacin (minimum inhibitory concentration [MIC] 0.25–1 mg/L) were first detected in 1991 from two patients who did not respond to ciprofloxacin treatment. By 1999, the incidence of decreased susceptibility to ciprofloxacin had increased to 23% with most of the infections found in patients who had a recent history of traveling to India or Pakistan.<sup>38</sup> Although such strains appear sensitive to fluoroquinolones by disk sensitivity testing, these strains are clinically resistant with prolonged fever clearance and decreased cure rates of approximately 50% (as compared to 97% for sensitive strains).<sup>42</sup> More recently, there have been sporadic reports of fully fluoroquinolone-resistant *S. Typhi* isolates.<sup>43</sup> There have also been rare reports of high-level resistance to ceftriaxone for *S. Typhi* and *S. Paratyphi A*.<sup>44</sup>

Results of a U.S. survey conducted in 2000 showed that 25% of *S. Typhi* isolates were resistant to at least one antibiotic and that 17% of isolates were resistant to five or more antibiotics.<sup>45</sup> Although none of the strains were fully resistant to quinolones, 7% of isolates were resistant to nalidixic acid. Those patients with multidrug resistant strains were more likely to have traveled to the Indian subcontinent. There have been recent reports of the resurgence of chloramphenicol-susceptible *S. Typhi* strains in locations such as Egypt,<sup>46</sup> India,<sup>47</sup> and Bangladesh.<sup>48</sup> In Indonesia, a country with one of the highest incidences of typhoid fever, *S. Typhi* and Paratyphi A isolates have remained sensitive to the usual antibiotics tested, including chloramphenicol and the fluoroquinolones.<sup>49</sup>

## Age

The age-specific attack rates of typhoid fever must reflect exposure to the organism and the development of a protective immune response. In endemic areas, children between the age of 1 and 5 years are at highest risk of developing *S. Typhi* infections due to waning passively acquired maternal antibody and lack of acquired immunity.<sup>50,51</sup> Osler observed that typhoid fever was primarily a disease of older adolescents and young adults, and most current data derived from studies of hospitalized patients in the developing world support this observation. However, in more recent years, prospective studies of outpatients in endemic areas have shown that even where the incidence in inpatients is highest in adolescents and young adults, the overall incidence of blood culture-confirmed disease is generally highest in children less than 9 years of age and declines significantly in late adolescence.<sup>4,17,19,52-54</sup>

The difference between hospital-based and outpatient studies may reflect the fact that older adolescents and young adults with *S. Typhi* infection generally become sicker than do children and require hospitalization more often than do children. Infants and children can certainly develop life-threatening typhoid fever, although the case-fatality rates for hospitalized children are generally lower than for adults.

## Source of Infection

*S. Typhi* infects only humans. Thus, all cases of typhoid fever could theoretically be traced back to another infected human. The stool and, less commonly, the urine of carriers and those with or recovering from acute infections are the source of the organism. It is generally believed that 1% to 4% of patients with acute typhoid fever become carriers,<sup>23</sup> but this rate is a function of the age and health of the patient. The carrier rate is higher in women and increases with increasing age and prevalence of gallbladder disease. Fecal carriers usually outnumber urinary carriers by 10 to 1, but in areas endemic for *Schistosoma haematobium*, urinary carriers are often more common. The carrier rate within communities varies considerably.

## Method of Transmission

The infection is most commonly acquired by ingestion of contaminated food or water but may rarely be transmitted by direct finger-to-mouth contact with the feces, urine, respiratory secretions, vomitus, or pus from an infected person. The stools of chronic carriers usually contain from  $10^6$  to

$10^9$  organisms per gram. *S. Typhi* can survive for several weeks in water, ice, dust, dried sewage, and on clothing, but survives in raw sewage for less than a week. It can also survive and multiply in milk or milk products without altering the appearance of the milk.

Food can be infected directly by water used to wash it or prepare it, by carriers, by fomites and dust, and probably by flies. In many cases, the initial concentration of organisms is too low to cause human disease, but under optimal environmental conditions the organisms can multiply in food. In the case of shellfish such as oysters or mussels, the polluted water in which they live may not have a high enough concentration of organisms to cause disease in a swimmer who ingests small amounts of water. However, since the shellfish filters up to 50 gallons of water per day and concentrates the microbial content, the aficionado of raw shellfish from polluted water may be presented with an enormous dose of *S. Typhi*.

In August 2000, the Ohio Department of Health reported sexual transmission of *S. Typhi* in a cluster of nine cases (seven culture-confirmed) in men in Ohio with no recent travel abroad, all but one of whom reported having had sexual contact with one asymptomatic male *S. Typhi* carrier.<sup>55</sup>

## Factors That Influence Infectivity

Studies done in human volunteers using the Quail strain of *S. Typhi* showed that, in healthy previously unvaccinated male adults, ingestion of  $10^5$  organisms led to clinical disease in 25% of volunteers (median infective dose  $ID_{25}$ ), ingestion of  $10^7$  organisms caused disease in 50% ( $ID_{50}$ ), and  $10^9$  organisms caused disease in 95% ( $ID_{95}$ ).<sup>56,57</sup> As the number of organisms increased, the attack rate increased, the incubation period decreased, but the clinical syndrome was unchanged. Nothing is known about the relationship between differences in strains of *S. Typhi* and infectivity except that strains that do not have Vi antigen are less infective and less virulent. A gastric pH of less than 1.5 will kill most of the organisms,<sup>58</sup> and those patients who chronically ingest antacids, have had a gastrectomy, or have achlorhydria due to aging or other reasons require lower numbers of organisms to produce clinical disease.

The genetic makeup of the host undoubtedly plays a role in susceptibility to infection. Studies are beginning to show associations between human lymphocyte antigen (HLA) types and susceptibility to infection, but it is not known if they are reproducible in other settings. In a study conducted in Vietnam, major-histocompatibility-complex alleles were associated with both susceptibility—HLA-DRB1\*0301/6/8, HLA-DQB1\*0201-3, and TNFA\*(-308)—and resistance—HLA-DRB1\*04, HLA-DQB1\*0401/2 and TNFA\*1(-308)—to typhoid fever.<sup>59</sup>

Although there is an increased incidence of nontyphi *Salmonella* in individuals with human immunodeficiency virus (HIV) infection, reports about the association between typhoid fever and HIV infection have been inconclusive.<sup>60,61</sup> Parenteral vaccination confers a fairly strong immunity, which may be overcome by increasing the infecting dose.

## PATHOGENESIS AND PATHOLOGY

The hallmark of typhoid fever is bacterial invasion of, and multiplication within, the mononuclear phagocytic cells in

the liver, spleen, lymph nodes, and Peyer's patches of the ileum. Our knowledge of the sequence of events following ingestion of an infective dose of *S. Typhi* is derived from studies of human volunteers and chimpanzees experimentally infected with *S. Typhi* and of mice infected with *Salmonella enteritidis* and *Salmonella* Typhimurium. However, this information is incomplete, and the theories of pathogenesis are not well substantiated.<sup>14,56</sup> For example, there is still no well-documented explanation of the pathogenesis of the mental confusion and other central nervous system manifestations that led to the disease being called typhoid.

### Proposed Sequence of Events

#### Mucosal Penetration

After ingestion, the organisms pass through the upper gastrointestinal tract to the small intestine, where they either invade directly or multiply for several days before invading. Since fewer than 5% of the villi have organisms attached, it is hypothesized that there are specific receptor sites on the villi, but these receptors have not been identified. Stool cultures are positive for several days after *S. Typhi* ingestion and then become negative until after the onset of clinical illness. Human volunteer studies have shown that invasion can take place in the jejunum, and animal studies suggest that it occurs in the ileum. The M cells, epithelial cells that overlie the Peyer's patches, are the potential sites where *S. Typhi* is internalized and transported to the underlying lymphoid tissues.<sup>62</sup> After penetration, the organisms pass to the intestinal lymphoid follicles and the draining mesenteric lymph nodes; some also pass into the systemic circulation where they are filtered out by the reticuloendothelial cells of the liver and spleen. The salmonellae are able to prevent acidification of the phagosomes, survive, and multiply within the mononuclear phagocytic cells of the lymphoid follicles, lymph nodes, liver, and spleen. At this stage, there are subtle degenerative, proliferative, and granulomatous changes in the villi, crypt glands, and lamina propria of the small bowel and in the mesenteric lymph glands. These changes are reversible and unassociated with clinical symptoms.

#### Dissemination and Organ Invasion

At a critical point (which is probably a function of number of bacteria, bacterial virulence, and the host's immune response), a sufficient number of organisms and possibly other mediators that induce clinical symptoms are released from this sequestered intracellular habitat in the intestinal and mesenteric lymph system and pass through the thoracic duct and into the general circulation. This marks the end of the incubation period, which may last from 3 to 60 days, but is usually 7 to 14 days.

During this bacteremic phase, the organisms may invade any organ but are most commonly found in the liver, spleen, bone marrow, gallbladder, and Peyer's patches in the terminal ileum.<sup>56,63</sup> They invade the gallbladder either directly from the bloodstream or from the bile and then reappear in the intestine, where they are excreted in the stool and reinvade through the intestinal wall. At most tissue sites the organisms are again taken up by, and multiply within, the mononuclear phagocytic cells.

**FIGURE 17-2** A typhoid nodule in the liver during the stage of active invasion. This lesion is principally composed of macrophages (center) with variable numbers of lymphocytes and plasma cells (periphery). (×305.) (Courtesy of the Armed Forces Institute of Pathology, Neg. No. 72-4603.)

#### Pathology

The basic histologic finding in typhoid fever is infiltration of tissues by macrophages (typhoid cells) containing bacteria, erythrocytes, and degenerated lymphocytes. Aggregates of these macrophages are called typhoid nodules (Fig. 17-2). They are most commonly found in the intestine, mesenteric lymph nodes, spleen, liver, and bone marrow, but may be found in the kidneys, testes, and parotid glands.

#### Intestine

In the intestine, there are four classic pathologic stages. *Hyperplastic* changes begin during the first week of illness and primarily involve Peyer's patches of the ileum and solitary lymphoid follicles of the cecum, but may involve any lymphoid tissue in the intestine. Almost all infiltrative cells are mononuclear; typhoid nodules are common. If the hyperplasia does not resolve, *necrosis* of the intestinal mucosa develops, usually after 7 to 10 days of clinical illness (Fig. 17-3). *Sloughing* of the mucosa follows and results in the development of an *ulcer*, which may bleed (see Fig. 17-3). The ulcers conform in shape and distribution to the location of the lymphoid follicles are largest in the ileum, and are almost always found on the antimesenteric border of the intestines. These ulcers may perforate into the peritoneal cavity.<sup>64</sup> Perforations are single and measure less than 1 cm in 80% of cases, and 90% are found within 60 cm of the ileocecal valve. When healing takes place, it is usually complete, without scarring.

#### Mesenteric Lymph Nodes, Spleen, and Liver

In the mesenteric lymph nodes, the sinusoids are enlarged and distended by large collections of macrophages and reticuloendothelial cells. The nodes become soft and swollen and often contain areas of focal necrosis. The spleen is enlarged, red, soft, and congested. Its serosal surface may have

**FIGURE 17-3** Peyer's patches in the ileum showing several stages in a single specimen. *A*, Active ulceration. *B*, Necrosis. *C*, The sloughing of necrotic tissue has left the muscularis bare. (Courtesy of the Armed Forces Institute of Pathology, Neg. No. 64-3208-2.)

a fibrinous exudate. Microscopically, the red pulp is congested and contains typhoid nodules. The liver is usually enlarged. Hypertrophy and hyperplasia of the Kupffer cells produce the typhoid nodules. There is frequently focal hepatic necrosis and cloudy swelling of hepatocytes. The gallbladder is usually slightly hyperemic and may, in rare instances, show evidence of cholecystitis.

### Other Organs

These are less frequently involved during typhoid fever and usually have lesions attributed to toxic factors. The heart may be flabby with dilated ventricles, and microscopically there is often a nonspecific pattern of necrosis with degeneration and fatty infiltration of the myocardial cells. The lungs may develop an interstitial pneumonitis and bronchitis, and skeletal muscles may show Zenker's degeneration. The most common lesion found in the kidneys is swelling and albuminous degeneration of the proximal tubular epithelium, but interstitial nephritis, glomerulonephritis, and pyelonephritis have been noted. Central nervous system changes have been poorly described, but ring hemorrhages, capillary thrombi, perivenous demyelinating leukoencephalitis, and meningitis have been reported. Occasionally, focal lesions such as osteomyelitis, brain abscess, and spleen and liver abscesses have been reported. These lesions are almost always characterized by a polymorphonuclear instead of a mononuclear response. *Salmonellae* stimulate phagocytosis of neutrophils, red blood cells, and platelets by histiocytes within the bone marrow stroma.<sup>65</sup> This may be one of the mechanisms behind the pancytopenia commonly seen in typhoid fever.

### Pathogenesis of Organ Dysfunction and Toxemia

A hypothesis for the pathogenesis of typhoid fever must explain (1) the inflammatory and necrotic changes at the sites of multiplication of the organism in the intestine, liver, spleen, and lymph nodes; (2) the prolonged pyrexia and toxemia; and (3) the pathologic changes and functional derangements in organs such as the heart, lungs, brain, and kidneys, where typhoid nodules and *S. Typhi* are generally not found.

Until the 1970s, most authorities thought that the necrotic changes in the intestine, liver, spleen, and lymph nodes were the result of tissue hypoxia secondary to small vessel occlusion by typhoid nodules, and that the systemic manifestations and dysfunction of other organs were caused

by circulating endotoxin.<sup>66</sup> There is evidence that neither small vessel occlusion nor circulating endotoxin play a major role in the pathogenesis of typhoid fever.<sup>67,68</sup>

### Endotoxin

The role of endotoxin in the pathogenesis of typhoid fever is unclear.<sup>69</sup> Investigators at the University of Maryland showed that when *S. Typhi* endotoxin was initially injected into human volunteers, it produced chills, fever, headaches, myalgias, anorexia, nausea, thrombocytopenia, and leukopenia, as in typhoid fever.<sup>66</sup> After these volunteers had received repeated injections of endotoxin, they became unresponsive (tolerant) to it, but when the tolerant subjects were challenged with *S. Typhi*, they developed classic typhoid fever. Since typhoid fever is an unrelenting, sustained illness when not treated with antibiotics, the fact that the volunteers developed tolerance to endotoxin suggests that circulating endotoxin does not cause the symptoms and signs of naturally acquired typhoid fever. Furthermore, the facts that endotoxin-tolerant volunteers developed typhoid fever after rechallenge, and that circulating endotoxin as detected by limulus assay is not present in many patients with typhoid fever, make it even less likely that circulating endotoxin plays a major role in the pathogenesis of the disease.<sup>68</sup>

### Immune Complexes and Other Immunologic Reactions

Several investigators have found circulating immune complexes in patients with typhoid fever, and others have noted immune complexes in renal biopsy specimens taken from typhoid patients with glomerulonephritis and nephrotic syndrome. The significance of these complexes is unknown. Other investigators have hypothesized that some of the less common central nervous manifestations of typhoid fever, such as Guillain-Barré syndrome, perivenous leukoencephalitis, and transverse myelitis, are due to an immune reaction, but there is no good evidence to support these hypotheses.

### Disseminated Intravascular Coagulation

Although there have been several reports of clinically classic disseminated intravascular coagulation (DIC) in typhoid patients, this is a rare complication. On the other hand, many patients with *S. Typhi* infections have laboratory evidence of DIC without bleeding and may have localized DIC within organs.<sup>68</sup>

## Metabolic and Nutritional Factors

Various authors have suggested that anemia, vitamin deficiencies, zinc and other trace metal deficiencies, thyroid dysfunction, tryptophan metabolites, other amino acids, and the time of day that infection occurs or treatment is initiated are all important in the pathogenesis of the disease and the host's ability to mobilize adequate defenses. Although it is likely that many of these factors may be important in determining the ultimate expression of the disease, it is unlikely that any of them are the major determinants of how the disease is expressed or how the host defends against the infection.

## Proposed Pathogenesis

The unique feature of typhoid fever is the relationship between *S. Typhi* and macrophages in the liver, spleen, intestinal lymphoid follicles, and mesenteric lymph nodes. Macrophages can produce an array of functionally active cytokines. These include tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 (IL-1), and interferon- $\alpha$  and - $\beta$  (IFN- $\alpha$ , IFN- $\beta$ ). Macrophages are also an important source of arachidonate metabolites and reactive oxygen intermediates. These macrophage products can cause cellular necrosis, recruitment of other inflammatory cells, stimulation of the immune system, vascular instability, initiation of the clotting mechanism, bone marrow depression, fever, and other abnormalities associated with typhoid fever. It is likely that *S. Typhi* endotoxin stimulates the macrophages to release these substances, which locally mediate the intestinal and hepatocellular necrosis found in the disease, and which, when released systemically, cause most of the other manifestations of the disease.<sup>69</sup>

Although immune complexes, other immune reactions, and metabolic disturbances probably cause some of the less common manifestations of the disease, it is doubtful that they play a significant role in the pathogenesis of the major features.

## IMMUNOLOGIC RESPONSE

Typhoid fever induces both systemic and local humoral and cellular immune responses. Although there have been many descriptive studies of the immune responses associated with infection with *S. Typhi*, and with immunization with typhoid vaccines, the roles of specific immune mechanisms in the development of resistance to reinfection with *S. Typhi*, the pathogenesis of typhoid, and complete elimination of bacteria from infected persons have not been clearly established.<sup>70,71</sup> Some have suggested that infection with typhoid confers long-lasting immunity to reinfection, but the high incidence of typhoid fever in young adults in endemic areas and the results of volunteer studies indicate that this is not the case. Fifteen volunteers who had ingested  $10^5$  organisms and developed acute typhoid fever were rechallenged with  $10^5$  organisms (expected to cause infection in 25% of nonimmune persons) a mean of 20 months after the first infection. Five (33%) developed acute typhoid fever again (T.F. Woodward, personal communication). The fact that hospital-based studies indicate that the incidence of severe typhoid fever is higher in older adolescents and young adults than in young children suggests that an acquired immune response may play a role

in the pathogenesis of severe disease. Relapse may reflect the inadequate development of an appropriate anti-*S. Typhi* immune response.

## Antibodies

*S. Typhi*-specific secretory immunoglobulin A (IgA) in the small intestine may be important in determining whether mucosal penetration takes place. A study from India has reported that patients with typhoid fever have lower levels of IgA in intestinal secretions than do controls.<sup>72</sup> *S. Typhi*-specific IgA has been demonstrated in the feces and intestinal fluid of volunteers immunized with the oral typhoid vaccine, Ty21a.

Development of specific antibodies during typhoid fever has been well documented.<sup>72,73</sup> Circulating IgG, IgM, and in some cases IgA antibodies to *S. Typhi* O, H, Vi, and porin antigens have been identified. Not all persons with typhoid fever develop antibodies to these antigens. Fourfold titer rises to O, H, and Vi antigens were documented in 75%, 75%, and 40%, respectively, of volunteers experimentally infected with *S. Typhi*. Immunization with the Vi antigen vaccine and the oral vaccine, Ty21a (see following Vaccines section), respectively, induces antibodies to Vi antigen and O antigen (IgG and IgA), and immunization with the killed typhoid vaccines can induce antibodies to O, H, and Vi antigens. It has not been proven that these antibodies are responsible for the protective immunity found after administration of these vaccines. However, the developers of the Vi vaccine attribute the vaccine-induced protection entirely to antibodies against Vi antigen. Work has only recently begun to determine the fine specificity of antigen-specific antibody responses.

## Cellular Immune Responses

A major characteristic of typhoid fever is the activation of macrophages.<sup>73–75</sup> Phagocytosis is a major host defense mechanism, and substances released from macrophages, including cytokines, reactive oxygen intermediates, and arachidonic acid metabolites, probably play a significant role in the pathogenesis of the disease. Several small studies in India have suggested that patients who do not develop cell-mediated immunity as measured by the leukocyte migration inhibition test have an increased incidence of complications and relapse, but investigators in Sri Lanka using similar techniques did not find this relationship. Immune cells may also play an important role in the protective immunity induced by immunization, but this response has not been adequately characterized.<sup>76</sup> It has been proposed that the protective immunity induced by immunization with the oral typhoid vaccine Ty21a may be mediated by antibody-dependent cellular cytotoxicity involving IgA antibodies against *S. Typhi* and CD4+ T cells, since volunteers immunized with Ty21a have been shown to develop this immune response.

## CLINICAL MANIFESTATIONS

The clinical presentation of typhoid fever is variable, but nearly all patients have fever and most have a headache.<sup>77,78</sup> The range of clinical manifestations and severity of the illness varies, depending on the patient population. Clinicians who see outpatients in an endemic area of the developing world

will find that their typhoid patients are moderately ill, that fewer than 10% will require hospitalization, that complications are rare, and that the case-fatality rate will be less than 1%. Hospital-based physicians in the same area will see typhoid patients who are much sicker; have a greater range of symptoms, signs, and complications; and have a case-fatality rate that may range from 1% to 30%. If one sees typhoid patients in the developed world, nearly all patients will be hospitalized, but the clinical severity, complications, and case-fatality rates will be comparable to those in outpatients in the developing world. In many cases, the most severely ill patients will have been sicker for longer periods than those who are moderately ill, but this is not always so. The strain of *S. Typhi*, the number of organisms ingested, the general and nutritional condition and immunologic status of the patient, and, possibly, the genetic makeup of the host may influence the clinical presentation.

### Untreated Typhoid Fever

After ingestion of the organisms, 10% to 20% of patients will have transient diarrhea. These patients, as well as all others, remain asymptomatic during the incubation period, which usually lasts 7 to 14 days but can be as short as 3 days and as long as 60 days, depending on the number of organisms ingested. As the stage of sustained bacteremia develops, the incubation period ends and the patient notices the onset of fever, which classically increases daily in a stepwise fashion but may be remittent or sustained. At this point, the patient will usually have a flulike syndrome with headache and malaise and will frequently have a sore throat, anorexia, nausea, abdominal pain, and myalgias, but may have any of the symptoms listed in Table 17-3. By the end of the first week after the onset of symptoms, the fever is sustained, and the patient is often toxic and may have any of the symptoms and signs listed in Tables 17-3 and 17-4.

**Table 17-3** *Symptoms Expected on Admission in Hospitalized Typhoid Patients in Endemic Areas of the Developing World*

Symptom	Percent
Fever	99
Weakness	99
Anorexia	85
Headache	85
Dizziness	80
Abdominal pain	50
Nausea	50
Chills	50
Diarrhea	45
Constipation	40
Cough or chest discomfort	35
Vomiting	35
Myalgia/arthralgia	35
Confusion	25
Sore throat	20
Decreased hearing	15
Blood in stool or melena	12
Epistaxis	10
Dysuria	2
Seizures	2

**Table 17-4** *Physical Signs Expected on Admission in Hospitalized Typhoid Patients in Endemic Areas of the Developing World*

Common		Less Common	
Sign	Percent	Sign	Percent
Fever	98	Disorientation	25
Coated tongue	95	Relative bradycardia	15
Apathy	70	Rales or rhonchi	15
Hepatomegaly	50	Delirium	15
Abdominal pain	45	Severe toxicity	10
Rose spots	0–50	Decreased hearing	10
Moderate illness	45	Stiff neck	10
Toxicity	45	Stupor	2
Splenomegaly	35	Focal neurologic findings	1

The fever remains sustained during the second week and by the third week begins to come down spontaneously by lysis. Intestinal perforation or hemorrhage, or both, can occur at any stage of the illness, but these findings classically occur during the third week. The illness can go on for several months, although by the end of the fourth week the temperature usually returns to normal, and except for patients with metastatic foci in whom cholecystitis, osteomyelitis, and soft tissue abscesses may develop, most patients have recovered. It is at this stage that most relapses occur.

### Clinical Course and Manifestations in Patients Who Receive Antimicrobials

Antimicrobials shorten the course, reduce the rate of complications if begun early, reduce the case-fatality rate, and some may increase the relapse rate.<sup>78</sup> During volunteer studies in Maryland, more than 400 patients with typhoid fever were treated within 3 days of the onset of fever and the complication and case-fatality rates were zero.

### Symptoms

The approximate frequencies of symptoms and signs expected to be found in hospitalized patients in endemic areas of the developing world are summarized in Tables 17-3 and 17-4. Before hospitalization, most of these patients will have been ill for 6 to 12 days, most will have seen a health-care provider at some point, and most will have received short courses of antibiotics. Fever is universal and, although present daily, is usually higher in the late afternoon and evening. Chills and dull frontal or diffuse headaches are common. The headaches often prevent patients from sleeping comfortably. Most patients are anorectic. They complain of abdominal pain, but cannot localize it well. Both diarrhea and constipation are common; normal bowel function is unusual.<sup>50,77</sup> Children frequently have diarrhea. Bloody dysentery is occasionally encountered. The incidence of cough and chest discomfort varies considerably. Sore throats are common during the first week of illness, but less common later. Dysuria is more commonly encountered in parts of the world where *S. haematobium* is endemic. Epistaxis, which was a common finding in the preantibiotic era, is much less

common now. Seizures are occasionally reported, being more common in children less than 5 years of age. If the patient's family is interviewed, a history of intermittent confusion during peak illness is frequently reported.

## Signs

On physical examination, the patient is generally moderately ill to toxic; however, 10% to 15% of patients will be severely toxic and may be hyperpyretic. The patient will be apathetic, lying immobile in bed, often staring blankly, but will be arousable. About 10% of patients are severely agitated and 5% obtunded. Disorientation is common, as is frank delirium.<sup>50,77</sup> Stupor and coma are infrequent. If the patient is hypovolemic from blood loss or dehydration, hypotension or shock may be present. Characteristic gram-negative septic shock is uncommon on admission, but may occur after intestinal perforation, in patients with severe typhoid fever without obvious perforation, and as a preterminal event. Relative bradycardia, once considered to be a classic finding in typhoid fever, in actuality is encountered in fewer than 25% of patients.<sup>23,77</sup> Rose spots, which are blanching, red, maculopapular lesions measuring 2 to 4 mm, are most frequently found on the abdomen and chest, but can be found on the extremities and back.<sup>23</sup> Rose spots are less frequently found in dark-skinned patients. The tongue may be covered with a thick, "furry" white-to-brown coating that spares the bright red tips and edges. The incidence of respiratory findings varies, but signs consistent with bronchitis (15%) are more common than those of lobar consolidation (1% to 8%).

The abdominal examination is frequently difficult to interpret. In classic descriptions, the abdomen is said to be "doughy," and the examiner easily palpates loops of bowel filled with air and fluid and finds diffuse lower quadrant tenderness. In some reports, diffuse abdominal pain with moderate guarding has often been described.<sup>77</sup> Frequently, it is difficult for the examiner to be certain that perforation has not occurred. The spleen or liver is enlarged in 30% to 50% of patients, and although both organs can become quite large, more commonly they are moderately enlarged, with the liver palpable 2 or 3 cm below the right costal margin and the spleen palpable on deep inspiration or 1 or 2 cm below the left costal margin. They are both usually soft and moderately tender. Occult blood is found in the stool of 20% to 30% of patients.

## Complications and Unusual Manifestations

### Intestinal Perforation

Intestinal perforation occurs in about 3% of hospitalized patients. It usually occurs during the third week of illness, but can happen during the first week.<sup>64,79</sup> The patient with perforation has the usual symptoms of typhoid fever and complains of severe abdominal pain that is often localized to the right lower quadrant, but may be diffuse. Bowel sounds are absent in 50% of cases. About 75% of patients will have guarding, rebound tenderness, and rigidity, particularly in the right lower quadrant.<sup>50,64,80,81</sup> Some patients will have an absence of hepatic dullness because of free air in the abdomen, but a pneumoperitoneum is present on radiography in only 50% to 70% of patients. Perforation causes a marked sudden rise in

pulse, fall in blood pressure, and onset of severe pain. In most patients, the diagnosis is not difficult. However, as noted previously, approximately 25% of patients will not have classic findings of peritonitis and perforation, and in these patients the diagnosis is difficult. It is sometimes difficult to decide whether a patient has perforation, impending perforation, or just severe typhoid abdominal pain. In the appropriate clinical setting, a rising white blood cell count with a shift to the left is suggestive of perforation, but this probably occurs in fewer than half of the patients with perforation.

### Intestinal Hemorrhage

Intestinal hemorrhage occurs in up to 15% of cases. Patients may or may not be toxic. The bowel usually does not perforate, and bleeding is sometimes heavy enough to cause shock.<sup>50</sup> If blood replacement can keep up with losses, the hemorrhaging is usually a self-limiting process, not requiring surgery. About 25% of patients with typhoid fever have minor bleeding that does not require transfusion.

### Neuropsychiatric Manifestations

In the past 25 years, reports from India,<sup>82</sup> Papua New Guinea,<sup>21</sup> Indonesia,<sup>83,84</sup> and Africa (particularly Nigeria)<sup>85</sup> have documented a wide spectrum of neuropsychiatric manifestations of typhoid fever. In some series, half the patients have had disorders of mental status. The most common findings are disturbances of the level of consciousness that range from disorientation to delirium, obtundation, stupor, and coma. Delirium, stupor, and coma are grave prognostic signs associated with case-fatality rates that have exceeded 40%. Delirium often persists after the temperature and metabolic abnormalities have returned to normal, and there is no good explanation for its pathogenesis.

Other less commonly encountered central nervous system findings are seizures, typhoid meningitis, encephalomyelitis, transverse myelitis with spastic paraplegia, peripheral or cranial neuritis, and Guillain-Barré syndrome. Psychotic syndromes, including schizophrenia-like illnesses, mania, depression, and catatonia, have all been described, especially in Africa.

### Cardiovascular Manifestations

Myocarditis occurs in 1% to 5% of typhoid patients,<sup>86,87</sup> whereas nonspecific electrocardiographic changes occur in 10% to 15% of patients. Patients with myocarditis may have no cardiovascular symptoms or may have chest pains, congestive heart failure, arrhythmias, or cardiogenic shock. When myocarditis occurs in young children, it is frequently a serious complication. Electrocardiographic findings are the same as in any myocarditis. Pericarditis rarely occurs, but "peripheral vascular collapse" without other cardiac findings is increasingly being described. Deep venous and arterial thromboses are uncommon.

### Hepatobiliary Manifestations

Mild asymptomatic elevations of transaminases are common in typhoid fever.<sup>86,87</sup> Jaundice with or without major elevations

of hepatic enzymes occurs in 1% to 2% of patients, as does acute cholecystitis. Acute or chronic cholecystitis may occur months to years after an episode of typhoid fever. Culture of stones or bile yields *S. Typhi* in these cases.

### Genitourinary Manifestations

About 25% of patients excrete *S. Typhi* in the urine at some point during their illness.<sup>86,87</sup> Transient proteinuria is the most common urinary abnormality and in some cases is due to an immune complex-mediated glomerulonephritis. On occasion the glomerulonephritis may present as renal failure or nephrotic syndrome, and in these cases the prognosis is poor. In severely ill patients, acute tubular necrosis may develop, and in patients with severe intravascular hemolysis, which may or may not be associated with glucose-6-phosphate dehydrogenase (G6PD) deficiency, renal failure can occur. Both pyelonephritis and cystitis also occur in typhoid patients.

### Other Complications

DIC is rarely of clinical importance, but thrombocytopenia, hypofibrinogenemia, elevated prothrombin (PT) and partial thromboplastin times (PTT), and elevated levels of fibrin degradation products are found in most patients.<sup>68</sup> The hemolytic-uremic syndrome and severe intravascular hemolysis have been reported. Because of the sustained bacteremia, focal infections can develop at any site of the body, but these occur rarely. The most common sites of infection are in the bones (extremities, spine, ribs), but infections have been reported in the brain, liver, spleen, muscles, breast, thyroid, salivary glands, and cervical lymph nodes. In the past, thrombophlebitis, parotitis, and decubitus ulcers were common complications but they now occur rarely.

### Relapse

Relapse occurred in 5% to 10% of patients in the preantibiotic era, and although initial reports in the 1950s and 1960s suggested that relapse increased to 10% to 20% in antibiotic-treated patients, most series have not reported increased relapse rates in appropriately treated patients.<sup>88</sup> Fever generally returns about 2 weeks after the cessation of antibiotic therapy or, in untreated patients, about 2 weeks after defervescence. However, relapse can occur during convalescence when the patient is afebrile but is still symptomatic and on antibiotics, and it has been reported several months after the initial illness. The relapse syndrome is usually, but not always, milder than the initial syndrome.

### Typhoid in Children under 5 Years of Age

*S. Typhi* infections have been acquired congenitally, and there have been many case reports in neonates. The clinical presentation in children less than 5 years of age, and especially those less than 1 year of age, is less predictable than in adults.<sup>50</sup> It ranges from an extremely mild illness, often diagnosed as a viral infection, but treated with antimicrobials, to severe typhoid fever with hospital mortality rates reaching 30%. Children with typhoid fever frequently have diarrhea and vomiting, and up to 20% may have convulsions. Typhoid meningitis,

although reported in adults and older children, is found almost exclusively in children less than 5 years old. Paratyphoid fever, particularly in infants, may also cause severe disease with high case-fatality and complication rates. In Indonesia, paratyphoid in children is often caused by the multiple antimicrobial-resistant *S. Oranienburg*.

### Geographic Variations

Reports from India,<sup>82</sup> Papua New Guinea,<sup>21</sup> Indonesia,<sup>83,84</sup> and some areas of Africa<sup>85</sup> have described patients with abnormal levels of consciousness or shock who have a much higher case-fatality rate than those with normal mental status. These cases of severe typhoid fever with high mortality have rarely been reported from the Americas. It is not clear if the difference in severity is a function of the host, the bacteria, or epidemiologic factors. In areas of endemic schistosomiasis, a syndrome of prolonged, intermittent fever and *Salmonella* bacteremia associated with mild active chronic schistosomiasis has been documented. The pathogenesis of this syndrome is unknown; however, it may be linked to the abnormal immune response seen in chronic schistosomiasis or the tegmental attachment of bacteria to the adult schistosome worm. Chronic *Salmonella* urinary carriage is common in areas with endemic *S. haematobium* and is undoubtedly related to the obstructive uropathy of urinary schistosomiasis. These patients may experience intermittent fever and bacteremia secondary to the resultant pyelonephritis. Patients with opisthorchiasis (liver fluke infection) may have intrahepatic as opposed to gallbladder carriage, and these persons may have asymptomatic carriage or recurrent cholangitis.

### Chronic Carriers

A person who excretes the organism in the stool 1 year after the initial illness is considered to be a carrier. Although 20% of typhoid patients will excrete the organism for 2 months after the onset of illness and 10% for 3 months, only about 3% of patients go on to become carriers.<sup>23</sup> The prevalence is higher in females and in the elderly and is probably correlated with the prevalence of cholelithiasis. Most carriers are asymptomatic, and in some series up to 25% could not give a history compatible with acute typhoid fever. Persons with abnormalities of the genitourinary system, including schistosomiasis, have a much higher prevalence of urinary carriage than those with a normal system.

### Laboratory Findings

At the time of hospital admission, most patients will be moderately anemic, have an elevated erythrocyte sedimentation rate, and a platelet count reduced to about 150,000. The white blood cell count will often be about 5000/ $\mu$ L to 6000/ $\mu$ L, but may range from 1200/ $\mu$ L to over 20,000/ $\mu$ L. The differential count is usually normal or shifted slightly to the left, but there may be a relative lymphocytosis, especially later in the disease. The cerebrospinal fluid is usually normal in typhoid fever. Most patients will have a slightly elevated PT and PTT, decreased fibrinogen levels, and circulating fibrin degradation products. Serum enzymes, for example, aspartate transaminase (AST) and alanine transaminase (ALT), are usually elevated to

twice normal, as is the serum bilirubin. Hyponatremia and hypokalemia are commonly encountered but are usually not severe. Renal function is usually normal. The urine often has low levels of protein and a few white blood cells.

## DIAGNOSIS

The diagnosis of typhoid fever is suspected by the clinician, suggested by assays that identify *Salmonella* antibodies, antigens, or DNA, and confirmed by isolation of the organism. Widal's reaction is indicative of typhoid fever in only 40% to 60% of patients at the time of admission,<sup>89</sup> and although the organism can be isolated from 95% of patients, identification takes at least 18 hours and often 3 to 4 days.<sup>90,91</sup> Thus, investigations are under way to develop more sensitive laboratory methods for making the rapid, presumptive diagnosis of typhoid fever.

## Isolation of the Organism

Culturing bone marrow aspirates (BMAs) is the single most sensitive method of isolating *S. Typhi* from patients with typhoid fever.<sup>90,92,93</sup> The diagnosis of typhoid cannot be excluded, and the sensitivity of other diagnostic techniques cannot be established without a BMA culture. If a BMA culture cannot be obtained, culturing 8 to 15 mL of whole blood, intestinal secretions, and stool will identify 85% to 90% of patients with typhoid fever.<sup>92</sup> A major limitation of conventional culture techniques is that it takes a minimum of 48 hours, and often 72 hours, from specimen acquisition until identification of the organism in culture. Work carried out in Indonesia indicates that when the mononuclear cell fraction of blood is cultured, a procedure that concentrates organisms and presumably removes inhibitory serum factors, or when organisms are concentrated by lysis centrifugation, 100% of cultured organisms can be identified within 18 hours of specimen acquisition.<sup>94</sup>

BMA cultures are positive in 80% to 95% of patients, even if patients have been taking antibiotics for several days, and regardless of how long they have been ill.<sup>90,92,93</sup> The blood culture is positive in 40% to 80% of patients. When experimentally infected human volunteers had daily cultures prior to antibiotic therapy (the mean number of cultures was 5.8), only 75% had positive blood cultures. In the Dade County, Florida, epidemic (see previous Epidemiology discussion), only 55% of hospitalized patients with typhoid fever had positive blood cultures.<sup>23</sup> The sensitivity of blood cultures is greatest during the first week of illness, is reduced by prior ingestion of antibiotics, and is directly related to the quantity of blood cultured and the ratio of culture broth to blood. Repeating blood cultures may improve the yield. Reports from South Africa indicated that culturing blood clots in the presence of streptokinase was 50% more sensitive than culturing whole blood.<sup>95</sup> This finding was not confirmed in studies in Indonesia.<sup>93</sup> Culturing intestinal secretions using a duodenal string capsule has been shown to have a sensitivity of 60% to 80%.<sup>92,96</sup> The sensitivity can be improved by culturing two specimens and leaving the string capsule in overnight, and may increase during the third week of illness.<sup>96</sup> In a single study, culturing skin snips of Rose spots had a sensitivity of 63%.<sup>90</sup> A 1-g stool

culture is reportedly more sensitive than a rectal swab culture, but is more difficult to obtain. A single-admission rectal swab culture can be expected to detect *S. Typhi* in 30% to 40% of patients<sup>90,92</sup>; the sensitivity increases with the length of illness. Because of irregular shedding, several stool cultures may be necessary to identify carriers. Urine cultures are reported to be positive in 5% to 10% of patients, except in areas endemic for *S. haematobium*, where the positivity rate increases markedly. *S. Typhi* has also been isolated from the cerebrospinal fluid, peritoneal fluid, mesenteric lymph nodes, resected intestine, pharynx, tonsils, abscesses, bone, and other sites.

Bone marrow aspirates and blood are cultured directly into bottles containing liquid broth media. A subculture from the blood culture bottles may be isolated into Taurocholate Infusion Broth (0.5% bile salt broth with 5 g Na Taurocholate in 1 L nutrient broth). Cultures are then further subcultured to selective media such as XLD, MacConkey, or *Salmonella-Shigella* agar, from which suspect colonies are picked for identification. When colonies appear, they are identified by PCR using nested fliC and Vi-associated primers or, most commonly, by using standard biochemical reactions and incubation with specific antisera. A staphylococcal protein A coagglutination technique can be used to identify colonies as soon as they appear on culture plates.<sup>95</sup>

After isolation, the organism should be tested for antimicrobial sensitivity. If it is resistant to chloramphenicol, it should be checked for the presence of R plasmids encoding for multiple antibiotic resistance. So-called "quinolone-resistant" strains, which generally have minimum inhibitory concentrations of the fluoroquinolones within the susceptible range of the interpretive criteria of the NCCLS, are characterized by resistance to nalidixic acid.

## Serologic and Other Tests

### Widal's Test

The standard serologic test in use for the diagnosis of typhoid fever has been Widal's reaction, which measures agglutinating antibodies to the O and H antigens of *S. Typhi*. Numerous studies have shown that the sensitivity, specificity, and predictive values of this test vary dramatically among laboratories. This wide variation is caused by differences in patient populations, antigens, and techniques. Thus, if physicians do not know the sensitivity, specificity, and predictive values for the test in their laboratory and in their patient population, the results are almost uninterpretable. On the other hand, if these values are known, Widal's test can be of some use.

Widal's test is inherently nonspecific because (1) *S. Typhi* shares O and H antigens with other *Salmonella* serotypes<sup>15,23</sup> (see Table 17-2); (2) *S. Typhi* shares cross-reacting epitopes with other Enterobacteriaceae; and (3) H antibody titers remain elevated for long periods after infection or immunization. Widal's test has a low sensitivity because (1) a significant number of culture-positive patients never develop detectable antibody as measured by this test; and (2) in those who do develop an antibody titer, the titer frequently begins to rise before the onset of clinical disease, making it difficult to demonstrate a fourfold rise in titer.

Studies in endemic areas have shown the sensitivity of a single elevated O antibody titer ( $\geq 1:40$  in Mexico and Indonesia,  $\geq 1:480$  in Zimbabwe) to vary from 50% to 90% and the specificity of the same titer to vary from 70% to 99%. In Indonesia, an O antibody titer of 1:40 or greater measured by the rapid, Widal's slide agglutination test (results available to the physician within 45 minutes of specimen acquisition) was shown to have a positive predictive value of 96%.<sup>89</sup> Although not useful when negative, when the test was positive the health-care provider could be 96% certain that the patient had typhoid fever. A rapid tube test for *Salmonella* O9 antibody using magnetic particles has been reported.<sup>97</sup> The sensitivity of a single H titer is similar, but the specificity is much lower. In endemic areas, a fourfold rise in O or H antibody titer is generally found in fewer than 40% of culture-positive patients. In nonendemic areas, the sensitivity is usually the same as in endemic areas, whereas the specificity is generally higher. A Vi agglutination reaction has been used for screening for *S. Typhi* carriers. The reported sensitivity and specificity are 70% to 80% and 80% to 95%, respectively.

Rapid tests, which include the enzyme-linked immunosorbent assay (ELISA), dipstick assays, latex agglutination, and monoclonal antibodies, have been developed.<sup>98–100</sup> Although these tests are in use in some laboratories, they are not yet readily available for general use.

### DNA Probes and Polymerase Chain Reaction

DNA probes have been developed for identifying *S. Typhi* from bacterial culture isolates and directly from blood.<sup>101,102</sup> However, these tests are not yet commercially available. PCR assays have been utilized by a number of groups for rapid diagnosis of *S. Typhi* infection in blood specimens from patients with typhoid fever, but these also are not yet in routine clinical use.<sup>103–105</sup> Such assays, utilizing primers based on the flagellin gene and the Vi antigen, can be used to detect genomic *S. Typhi* DNA in 12 hours or less,<sup>106</sup> with a high degree of sensitivity and specificity.

## Differential Diagnosis

### Endemic Areas

During the first week of illness, it is difficult to clinically distinguish typhoid fever from many other febrile illnesses. Thus, the physician must suspect typhoid fever, order appropriate cultures, and consider treatment prior to obtaining bacteriologic confirmation. During the second week of febrile illness, the range of possibilities is narrowed, particularly if the other locally prevalent diseases that can cause prolonged fever are known. These include other bacterial diseases such as endocarditis, brucellosis, tularemia, tuberculosis, and abscesses; rickettsial infections such as typhus; protozoan infections such as malaria, visceral leishmaniasis, amebic liver abscess, and toxoplasmosis; viral infections such as influenza or dengue fever; and noninfectious diseases such as connective tissue diseases and lymphoproliferative disorders.

Physicians practicing in the tropics frequently see patients with fevers lasting for 7 to 10 days who have nonspecific clinical findings compatible with typhoid and negative bacteriologic tests and who recover either without antimicrobial treatment or after empirical treatment with a broad-spectrum antibiotic.

It is likely that many of these patients do have viral infections. It should be noted that the spleen in typhoid fever is generally considerably smaller and softer than the spleen in malaria.

### Developed Countries

Unless there is an epidemic, most cases will be imported. The physician must remember to take a travel history, suspect typhoid fever in febrile patients returning from endemic areas, and order appropriate cultures. The differential diagnosis will include those diseases prevalent in the areas visited, as outlined previously, and all other causes of prolonged fever. Typhoid should also be suspected in patients who have not traveled and who have prolonged fever.

If the diagnosis of typhoid fever is considered, and particularly if the patient is toxic or has had previous antibiotics, a bone marrow aspirate culture should be used as a primary diagnostic tool.

## TREATMENT

In most cases of typhoid fever, successful treatment requires prompt diagnosis, use of an appropriate antibiotic, and bed rest at home. In many endemic areas, more than 90% of patients are managed in this way, and case-fatality rates for such patients are less than 1%.<sup>86,107</sup> In some areas of Indonesia, India, Nepal, and a number of countries in Africa, 20% to 30% of patients with typhoid who are admitted to the hospital are severely ill, and unless they receive intensive care, appropriate doses of corticosteroids, and surgery, when indicated, may have case-fatality rates of 10% to 50%.<sup>21,83–85,108</sup> Management of hospitalized patients requires (1) proper use of antibiotics; (2) good nursing care; (3) adequate nutrition; (4) careful attention to fluid and electrolyte balance; (5) prompt diagnosis and treatment of intestinal perforation, intestinal bleeding, and other complications; and (6) the use of high-dose corticosteroids in severely ill patients.

### Antibiotic Selection

Medications that are appropriate for the treatment of typhoid fever include ampicillin, amoxicillin, cefotaxime, ceftriaxone, chloramphenicol, trimethoprim-sulfamethoxazole, or a fluoroquinolone.<sup>109</sup> Of these, fluoroquinolones have been found to result in the shortest fever-clearance times. Azithromycin has also recently been shown to be effective. Oral therapy is indicated for uncomplicated disease and parenteral therapy is required for severe illness. Choice of a specific antibiotic is based on the expected or known susceptibility of the organism. Caution must be applied when interpreting results of susceptibility testing. Although *S. Typhi* is often susceptible in vitro to drugs including cephalexin, aminoglycosides, furazolidone, and second-generation cephalosporins, use of these drugs has often resulted in treatment failure.

### Multidrug-Resistant Typhoid Fever

Infection acquired in India, Pakistan, and Egypt is routinely resistant to multiple antibiotics (ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole). For typhoid fever attributable to such strains, appropriate treatment includes a 10- to 14-day course of ceftriaxone or a 5- to 7-day course of ofloxacin or

ciprofloxacin, although more prolonged courses of treatment may be necessary. The widely available fluoroquinolones (ofloxacin, ciprofloxacin, and perfloracin) are all of equivalent efficacy; however, norfloxacin should not be used to treat typhoid fever because of suboptimal bioavailability. See the discussion under “Fluoroquinolones” regarding the use of fluoroquinolones in the pediatric population. Azithromycin may also be considered for the treatment of multidrug resistant strains.

### Quinolone-Resistant Strains

Treatment failures with fluoroquinolones have been reported in infections caused by nalidixic acid-resistant strains. Such relatively quinolone-resistant strains have emerged as an increasingly important clinical problem in the last decade, becoming endemic in a number of areas including southern Vietnam and northern India.<sup>110,111</sup> Although optimal treatment for quinolone-resistant uncomplicated typhoid fever has not been established, options include azithromycin (8–10 mg/kg/dose) for 7 days, a third-generation cephalosporin given for 10 to 14 days, or a fluoroquinolone (20 mg/kg/day) given for 10 to 14 days (given that one can generally achieve levels of the drug that surpass the MIC). Shorter courses of fluoroquinolones have been less satisfactory in the treatment of quinolone-resistant strains.<sup>110</sup> A randomized controlled study found that azithromycin 20 mg/kg/day for 5 days was more effective than ofloxacin 8 mg/kg/day for 5 days for nalidixic acid-resistant enteric fever.<sup>112</sup> For severe disease with quinolone-resistant strains, ceftriaxone or cefotaxime are recommended; fluoroquinolones may be used as a second-line alternative. In the case of *S. Typhi* strains with MIC values of ciprofloxacin of  $\geq 2$   $\mu\text{g/mL}$ , a third generation cephalosporin or azithromycin should be used.

### Specific Antibiotics

#### Chloramphenicol

Prior to the emergence of drug-resistant strains of *S. Typhi*, chloramphenicol was the most effective and widely used antibiotic for treating typhoid fever patients and the standard against which all other antibiotics were judged. It produces defervescence and relief of symptoms in most patients within 3 to 4 days, reduced the pre-antibiotic era case-fatality rates of 10% to 15% to 1% to 4%, and cures approximately 90% of patients with chloramphenicol-sensitive strains.<sup>87,107</sup> Most studies have shown that in acute chloramphenicol-sensitive *S. Typhi* infections, chloramphenicol produces more rapid defervescence than do ampicillin, amoxicillin, and trimethoprim-sulfamethoxazole, and a higher rate of clinical cure than ampicillin. However, the emergence of multidrug-resistant typhoid fever (MDRTF) has lessened its usefulness. In addition, it does not reduce the relapse rate, has no effect on the convalescent excretor or chronic carrier, and causes aplastic anemia in 1 in every 10,000 to 50,000 patients. In the treatment of susceptible strains, chloramphenicol has the advantage of being inexpensive and rarely associated with any short-term side effects noticeable to the patient.

#### Fluoroquinolones

In the late 1980s and 1990s, with the emergence of MDRTF, fluoroquinolones, including ciprofloxacin, norfloxacin, and

ofloxacin, were shown to be effective agents for the treatment of typhoid fever.<sup>113–117</sup> For typhoid fever caused by susceptible strains, evidence suggests that the fluoroquinolones provide the most effective therapy for typhoid fever even when given as short courses of 3 to 7 days. Pooling data from 17 clinical trials conducted with ciprofloxacin, ofloxacin, fleroxacin, and perfloracin, the mean fever clearance time was less than 4 days and cure rates were greater than 96%.<sup>116</sup> Most recent studies suggest that, as compared to chloramphenicol, trimethoprim-sulfamethoxazole, and even the third-generation cephalosporins, the fluoroquinolones act more rapidly and have lower rates of stool carriage.<sup>117–119</sup> Relapse after treatment with fluoroquinolones has generally been reported to be less than that with chloramphenicol or the cephalosporins.

Use of fluoroquinolones in animal models has resulted in cartilage damage and, thus, according to Food and Drug Administration (FDA) product labeling, use has generally been contraindicated in patients less than 18 years of age. Perfloracin, a fluoroquinolone once widely used in France, has been associated with several cases of presumed arthropathy in the pediatric population.<sup>120</sup> However, overall, the data acquired on the short-term use of fluoroquinolones to treat infections such as typhoid fever and dysentery in the pediatric population has been reassuring with regard to safety and tolerability.<sup>121</sup> Thus, in specific situations, such as in the treatment of typhoid fever caused by multidrug resistant strains, their use is considered to be justified by many infectious disease experts.<sup>121</sup>

### Third-Generation Cephalosporins

Studies in animals indicate that the third-generation cephalosporins are quite effective in the acid environment of reticuloendothelial cells and that particularly cefoperazone, but also ceftriaxone, is excreted in high concentration into the biliary tract. The *in vivo* activity of these compounds against *S. Typhi* has been attributed to these characteristics. Ceftriaxone, cefixime, cefotaxime, and cefoperazone (all third-generation cephalosporins) have acceptable efficacy in the treatment of typhoid fever. In the past 2 decades, these compounds, particularly ceftriaxone and cefoperazone, have been shown in a number of studies to be at least as effective in treating typhoid fever as chloramphenicol.<sup>122</sup> The third-generation oral cephalosporin cefixime has been shown to be effective in the treatment of uncomplicated typhoid fever due to MDRTF *S. Typhi*, although short-course treatment with cefixime appears less effective than short-course treatment with ofloxacin.<sup>123</sup>

### Ampicillin, Amoxicillin, and Trimethoprim-Sulfamethoxazole

These drugs are all effective against *S. Typhi* with R plasmid-mediated resistance to chloramphenicol, but R plasmid-mediated resistance to ampicillin and to trimethoprim is increasingly recognized. The dosage regimens listed in Table 17-5 will provide the best available cure rates and the lowest relapse rates. Treatment with these antibiotics does not prevent gallbladder carriage.

**Table 17-5** Antimicrobial Therapy of Typhoid and Paratyphoid Fever

Antibiotic	Route of Administration*	Daily Dosage (mg/kg/day)	Doses per Day	Duration (Days)
Chloramphenicol	PO/IV	PO:50–75, IV:100 (Usual adult dose: 2 g/day)	4	14–21
Trimethoprim-sulfamethoxazole	PO/IV	8 <sup>†</sup> (Adults 320 <sup>†</sup> mg/day)	2	14
Amoxicillin	PO	75–100	3	14
Ampicillin	IV/IM	100	4	10–14
Ceftriaxone	IV	50–75 (Adults: 2–4 g/day)	1	10–14
Cefotaxime	IV	40–80 (Adults: 2–4 g/day)	3	10–14
Cefixime	PO	15–20 (Adults: 200–400 mg/day)	2	10–14
Ciprofloxacin or Ofloxacin <sup>§</sup>	PO/IV	15–20 <sup>†</sup>	2	5–14 <sup>§</sup>
Azithromycin	PO	8–10 (Adults: 500 mg/day)	1	7

\*For severe typhoid, parenteral therapy is indicated.

<sup>†</sup>The dosage refers to the trimethoprim component.

<sup>‡</sup>The generally recommended dosage is 15 mg/kg/day except for treatment of quinolone-resistant strains, for which 20 mg/kg/day is recommended.

<sup>§</sup>For uncomplicated typhoid fever, the generally recommended duration is 5–7 days for fully susceptible strains (3-day courses also shown to be effective, particularly for epidemics); 5–7 days for multidrug-resistant strains; 10–14 days for quinolone-resistant strains. For severe typhoid fever, 10–14 days is recommended.

## Azithromycin

Although not yet approved by the FDA for treating typhoid, there are considerable data indicating that the macrolide azithromycin provides an alternative therapeutic option for the treatment of uncomplicated typhoid fever. It possesses in vitro activity against *S. Typhi*.<sup>124,125</sup> It has been studied in a number of randomized comparative clinical trials. In India, a randomized comparative study in 77 adults demonstrated that 7 days of azithromycin was at least as effective as 14 days of chloramphenicol in treating typhoid fever with susceptible strains (100% vs. 94% cure at 14 days post start of treatment with no prolonged fecal carriage in either group). In Egyptian children aged 4 to 17 years, 31 of 34 children (91%) were cured after 7 days of azithromycin and none had relapses as compared to 29 of 30 (97%) cured with ceftriaxone with 4 (14%) relapses.<sup>126</sup> In a randomized controlled comparison of 5 days of azithromycin or 5 days of ofloxacin in 88 adult patients with multidrug-resistant or nalidixic acid-resistant typhoid fever, those treated with azithromycin had a shorter fever clearance (135 vs. 174 hours) and had no positive fecal cultures at the end of treatment, as compared to 41% of those treated with ofloxacin.<sup>112</sup> A comparative study in Egypt of azithromycin and ciprofloxacin, each given for 7 days, demonstrated that the drugs were similarly effective clinically and against the infectious agent.<sup>115</sup>

## Other

Although effective in vitro against *S. Typhi*, sulfonamides, tetracyclines, and aminoglycosides are ineffective in vivo, probably because they are ineffective at the low pH of the phagolysosomes that contain intracellular *S. Typhi* in reticulo-endothelial cells. Aztreonam has had a variable success rate and thus is not considered first-line therapy.

## Supportive, Nutritional, and Nursing Care

Toxic patients with typhoid fever are frequently immobile or agitated, anorectic or incapable of eating, and highly febrile. They must be turned and bathed frequently, fed intravenously or carefully by mouth, and cooled with a cooling blanket or by using tepid sponge baths supplemented by a fan to enhance evaporation. They must be protected against aspiration and observed for signs of intestinal perforation or hemorrhage and shock. Many authorities recommend avoidance of antipyretics, since they are reported to cause precipitous drops in temperature and hypotension; however, they may be used if the temperature remains over 39.5°C after other measures have been tried. Patients who do not have a paralytic ileus, suspected perforation, or severe abdominal pain should be encouraged to eat whatever they like, since maintenance of good nutritional status is more important than an unsubstantiated concern about some foods precipitating intestinal perforation or hemorrhage. Vitamin supplementation is recommended. Some patients may require total parenteral nutrition, but this is infrequent.

## Fluid and Electrolyte Balance

Most patients can be managed without intravenous therapy. Patients with severe typhoid fever have poor oral intake, high insensible water losses, and tend to become dehydrated with hyponatremia and hypokalemia. Vomiting or diarrhea exacerbates the situation. Initial fluid replacement therapy should provide for maintenance needs, insensible losses, and replacement for dehydration. A typical 50-kg patient who is not in shock will require 3 to 4 L of fluid the first day. Thereafter, records of input and output should be kept and used in managing the patient. If possible, electrolyte determinations should be performed frequently. If not possible, the patient should

receive liberal quantities of sodium chloride and potassium unless renal failure is suspected.

### Corticosteroids

Since the observations of Woodward and colleagues in 1951,<sup>108</sup> the use of corticosteroids in severe typhoid fever has been controversial. Corticosteroids dramatically shorten the toxic febrile stage in typhoid fever, but until 1982 there was no proof that they reduced mortality. Studies in Indonesia by Hoffman, Punjabi, and colleagues have shown that prompt administration of high-dose dexamethasone reduces mortality in patients with severe typhoid fever without increasing the incidence of complications, carriers, or relapse among survivors.<sup>83,84</sup> The results of these studies have led to the recommendation by the Antimicrobial Agents Committee of the Infectious Diseases Society of America that patients with suspected typhoid fever who are delirious, obtunded, stuporous, comatose, or in shock (severe typhoid fever) should immediately receive dexamethasone or an equivalent corticosteroid.<sup>127</sup> After starting antimicrobial therapy, an initial dose of 3 mg/kg of dexamethasone should be administered by slow intravenous infusion over 30 minutes. This is followed by 1 mg/kg of dexamethasone given at the same rate every 6 hours for eight additional doses, the total duration of corticosteroid therapy being 48 hours. Patients with normal mental and circulatory status do not require corticosteroids, but those with borderline mental or circulatory status should be monitored every 15 minutes in an intensive care unit. If their condition deteriorates, they should receive dexamethasone or an equivalent corticosteroid immediately because a delay in institution of this therapy has been shown to significantly increase mortality.

### Treatment of Complications

#### Intestinal Perforation

Generalized peritonitis and large quantities of pus are often found in patients with intestinal perforation, while walling off of the perforation is infrequent. If a well-trained surgeon, anesthesiologist, and operating room staff and the necessary equipment are available, operative management of typhoid perforation is indicated.<sup>79-81</sup> If these are not available, the choice between operative and nonoperative management is controversial and must be individualized.

In all cases the patient should be started on appropriate antibiotics for *S. Typhi* depending on the local resistance pattern; placed on nasogastric suction; resuscitated with fluids, blood, and oxygen as needed; and given corticosteroids, if severely toxic. In addition, further antibiotics need to be added to provide coverage for the gram-negative rods and anaerobes that constitute the intestinal flora.

It is preferable to stabilize the patient before surgery, but the operation should not be delayed for more than several hours after diagnosis. At operation, the ileum, as well as the cecum and proximal large bowel, should be examined for perforations, and one of several procedures should be performed; for example, intestinal resection and primary anastomosis, or wedge excision, or debridement of the ulcer with primary closure of the perforation. Most surgeons will suture sites of impending perforation with serosa-to-serosa approximation. The peritoneal cavity is

then lavaged and the abdomen is closed, with or without drainage. Standard postoperative care is practiced. As the interval between perforation and surgery increases and the preoperative status of the patient worsens, the case-fatality rate increases. Mortality rates of 10% to 32% have been reported.

#### Intestinal Hemorrhage

In most cases, intestinal hemorrhage, even when massive, can be managed with general supportive care and vigorous replacement of blood. Occasionally the use of platelets, fresh-frozen plasma to replace clotting factors, or intestinal resection will be necessary, but this is uncommon. If the patient does not have an abnormal level of consciousness or shock, the case-fatality rate will be less than 1%.

#### Other Complications

Renal failure, pneumonia, respiratory failure, myocarditis, arrhythmias, cardiac failure, shock, meningitis, localized abscesses, arthritis, osteomyelitis, hemolytic anemia, and cholecystitis are all occasionally encountered and should be managed with antimicrobials and standard medical or surgical practices.<sup>86</sup> DIC may sometimes be clinically significant, in which case platelet, blood, and clotting factor transfusions may be necessary. There is no evidence that heparin therapy is useful in typhoid.

#### Relapse

Relapse should be treated in the same way as the first attack.

#### Management of Carriers

In the absence of cholelithiasis, the majority of carriers can be cured by a prolonged course of antibiotics targeted to the susceptibility of the organism. Cure rates of approximately 80% have been reported with oral ampicillin or amoxicillin 100 mg/kg/day, plus probenecid 30 mg/kg/day taken for 3 months; trimethoprim-sulfamethoxazole, one double-strength tablet twice daily, for 3 months; or 750 mg of ciprofloxacin twice daily for 4 weeks.<sup>128-130</sup> In the presence of cholelithiasis, the preceding regimen should be tried before surgical intervention is considered, but in most cases antimicrobial treatment alone will not be successful and cholecystectomy, as well as the same antimicrobial regimen, is required. A cure rate of 80% to 90% can be obtained with combined surgical and antimicrobial treatment. In some patients with cholelithiasis, *Salmonella* carriage can be eliminated with ciprofloxacin alone.<sup>129,130</sup> Some chronic urinary carriers of *S. Typhi* are infected with *Schistosoma haematobium*. The schistosomiasis should be treated first, and then the patient should receive an antibiotic.

#### Prognosis

The prognosis is dependent on the patient population and the geographic area of the world. In an epidemic in developed countries, patients will generally be seen and treated promptly, have a case-fatality rate of less than 1%, and have a low incidence of complications. The majority of patients in

endemic areas will be treated as outpatients and have case-fatality and complication rates comparable to those expected in an epidemic in developed countries.

In Central and South America, hospitalized patients are reported to have mortality rates of less than 1%. In some endemic areas, including Indonesia, Nigeria, India, and Nepal, severe typhoid fever (abnormal level of consciousness or shock) is common among hospitalized patients. These patients with severe typhoid fever may have a mortality rate as high as 50% if they are not treated with high-dose dexamethasone therapy.<sup>21,82–85,108</sup>

Nearly all studies report much lower complication, case-fatality, relapse, and carrier rates with paratyphoid fever. There have been a number of reports of particularly severe paratyphoid fever in young children and infants, in whom complication and case-fatality rates have been similar to those in patients with typhoid fever.

## PREVENTION AND CONTROL

### Nonendemic Areas

In developed countries, prevention is now the responsibility of sanitation, water supply, and public health officials. Individuals need not take any special precautions. Chronic carriers should be identified and treated. In the past, considerable time and money were devoted to screening food handlers, but in many countries this is no longer considered necessary. In the event of an epidemic, the source of the infection must be identified and eliminated, and any breakdown in the water delivery and sewage systems must be repaired. The general populace must be informed of the need to adhere to standard hygiene practices.

### Endemic Areas

People can minimize their chances of developing enteric fever by paying careful attention to the quality of the food and water that they ingest and by receiving immunizations. *S. Typhi* in water is killed by heating to 57°C, iodination, or chlorination. *S. Typhi* in food is killed at the same temperature, but the food must be heated uniformly for several minutes. Travelers to or residents of endemic areas should drink only boiled or bottled water; avoid eating fresh, uncooked vegetables or unpeeled fruit that has not been thoroughly

washed in iodinated or chlorinated water; and use discretion when eating in restaurants or at food stalls. Reduction of endemicity will depend on improvements in water supply and sewage systems and education of the populace as to proper hygiene and food and water preparation practices. Mass immunization can be extremely useful.

### Vaccines

In the United States, there are two vaccines currently available for immunization against typhoid: (1) the oral Ty21a vaccine, an oral, live, attenuated vaccine (Vivotif Berna vaccine, manufactured from the Ty21a strain of *S. Typhi* by the Swiss Serum and Vaccine Institute); and (2) the intramuscular ViCPS vaccine, a Vi capsular polysaccharide vaccine (Typhim Vi, manufactured by Aventis Pasteur). The efficacy of these vaccines is expected to be between 50% and 75%. See Table 17-6 for recommendations on usage. The intramuscular heat-phenol-inactivated vaccine (manufactured by Wyeth-Ayerst) has been discontinued and is no longer available for use. A Vi capsular polysaccharide-protein conjugate vaccine has recently been shown to be more effective than all other vaccines<sup>7,8</sup> and it is hoped that it will be introduced for general use soon. Vivaxim is a combined hepatitis A/typhoid fever vaccine (HA/Vi), which has been licensed for vaccination of travelers in Europe, but is not available in the United States.<sup>131</sup>

### Oral Ty21a Vaccine

The Ty21a vaccine, agalactose epimerase (gal E) mutant of *S. Typhi*, was developed by Germanier as an oral vaccine.<sup>2–4</sup> In contrast to the whole-cell vaccine, it has minimal to no side effects. In volunteers in Maryland, five to eight doses conferred 87% protection against an ID<sub>50</sub>. Field studies suggest an inverse relation between the level of transmission of typhoid in an area and protective efficacy. In 6- to 7-year-old Egyptians (incidence in controls, 46/100,000/year), the protective efficacy was 96% after 3 years.<sup>3</sup> In 6- to 21-year-old Chileans (incidence in controls, 103/100,000/year), the efficacy was 67% after 3 years,<sup>2</sup> and in 3- to 19-year-old Indonesians (incidence in controls, 1206/100,000/year), the efficacy of the liquid and enteric-coated formulations was 53% and 42% after 2.5 years, respectively.<sup>4</sup> The vaccine does not contain Vi antigen and is thought to induce a protective cellular immune response. However, the vaccine has not been

**Table 17-6 Dosage and Schedule for Typhoid Fever Vaccination\***

Vaccination	Age	Dose/Mode of Administration	No. of Doses	Dosing Interval	Boosting Interval
Oral, Live, Attenuated TY21a Vaccine					
Primary series	6 years or older	1 capsule <sup>†</sup> /oral	4	48 hours	Not applicable
Booster	6 years or older	1 capsule <sup>†</sup> /oral	4	48 hours	Every 5 years
Vi Capsular Polysaccharide Vaccine					
Primary series	2 years or older	0.50 mL/intramuscular	1	Not applicable	Not applicable
Booster	2 years or older	0.50 mL/intramuscular	1	Not applicable	Every 2 years

\*Per 2004 Centers for Disease Control and Prevention Recommendations.

<sup>†</sup>Administer with cool liquid no warmer than 37°C (98.6°F).

shown to induce either cellular or humoral immunity in children less than 2 years of age.<sup>132,133</sup> It is not recommended for use in children less than 6 years of age.

### Parenteral ViCPS Vaccine

This vaccine was developed and studied by Robbins and coworkers.<sup>5,6</sup> In 5- to 44-year-old Nepalese (incidence in controls, 654/100,000/year), a single injection of the vaccine was not associated with significant side effects and conferred a protective efficacy of 72% after 17 months.<sup>5</sup> In South African schoolchildren (approximate incidence in controls, 470/100,000/year), the Vi vaccine had a protective efficacy of approximately 64% during 21 months of surveillance.<sup>6</sup> The Vi vaccine was associated with an efficacy of 73% (95% confidence interval [CI], 32%–89%) in protecting against infection among 1260 students immunized before an outbreak of typhoid fever occurring in a middle school in the People's Republic of China and an efficacy of 71% (95% CI, –9% to 92%) in protecting 441 students immunized during the outbreak, results which support its use as a public health tool.<sup>134</sup> It is thought that antibodies to Vi antigen are responsible for the protective immunity. However, the Vi vaccine does not induce protective antibody levels in young children nor does it produce a booster response.<sup>135,136</sup> It is not recommended for use in children less than 2 years of age.

### Whole-Cell Typhoid Vaccines

These vaccines have now been discontinued from use. The first parenteral killed typhoid vaccine was introduced in 1896. By 1912, all U.S. military personnel were required to receive it, but it was not until the 1960s that the vaccine's efficacy was established in field trials.<sup>137</sup> The WHO sponsored trials in typhoid-endemic areas of Poland, Yugoslavia, Guyana, and the then Soviet Union, and demonstrated that both phenol- and acetone-inactivated vaccines offered 51% to 88% protection to children and young adults. The acetone-inactivated vaccine, which preserves Vi antigen, was moderately more effective than the phenol-inactivated vaccine. Studies at the University of Maryland showed that the same vaccines used in the WHO studies gave 67% protection to volunteers who ingested an ID<sub>25</sub> (10<sup>5</sup> organisms) of *S. Typhi*, but did not offer any protection to those who ingested an ID<sub>50</sub> (10<sup>7</sup> organisms).<sup>137</sup> The heat- and phenol-inactivated typhoid vaccines had been the only available vaccine for children younger than 2 years of age. However, the vaccines have been associated with a relatively high rate of adverse events, with local and systemic side effects reported in 25% to 50% of recipients<sup>138</sup> and their use has been discontinued in the United States.

### *S. Typhi* Vi Conjugate Vaccine

Given that the two licensed vaccines confer only a maximum of 75% protective immunity and do not protect or are not recommended for young children, this conjugate vaccine was developed and has shown promising results. *S. typhi* Vi conjugate vaccine (Vi-rEPA) is composed of Vi bound to a nontoxic recombinant protein which is antigenically identical to *Pseudomonas aeruginosa* exotoxin A (rePA).<sup>139</sup> Based on

initial demonstrations of safety and immunogenicity,<sup>140</sup> a double-blind, placebo-controlled, randomized trial was conducted in 11,091 children 2 to 5 years of age in 16 communes in Dong Thap Province, Vietnam (incidence in controls, 358/100,000/year).<sup>7</sup> The vaccine was safe, immunogenic, with a protective efficacy of 91.5% (95% CI, 77.1% to 96.6%;  $p < 0.001$ ) over 27 months of active surveillance. In all of the 36 children evaluated 1 month after the second immunization, there was a 10-fold increase in serum IgG Vi antibodies. During a subsequent 19-month period of passive surveillance, protective efficacy was 82.4% (95% CI, 22.3% to 99.1%).<sup>8</sup>

### Vaccine Recommendations

Routine typhoid vaccination should be given to laboratory workers likely to work with *S. Typhi*, household contacts of known *S. Typhi* carriers, and those traveling to or living in areas where typhoid is endemic. This includes most countries of the developing world. Routine vaccination is not recommended in those countries where the incidence is low, as in the United States and Europe, not even during disasters or for family contacts. During disasters or in refugee camps in endemic areas, mass immunization should be considered, recognizing that provision of safe food and water is of primary importance.

### Immunization

See Table 17-6 for schedule and dosage of vaccines, as recommended by the Centers for Disease Control and Prevention.

#### Ty21a

Children who are 6 years of age and older and adults should take one capsule every 2 days for a total of four capsules.<sup>109</sup> The capsule should be taken with cool liquid approximately 1 hour prior to intake of a meal. Capsules should be kept refrigerated.<sup>4</sup> The liquid formulation of Ty21a, which may be useful in administering the vaccine to children, is not available in the United States, but is used in many locations throughout the world. The vaccine manufacturer recommends reimmunization with the entire four-dose series every 5 years in the case of continued or renewed exposure to *S. Typhi*.

Since Ty21a is a live attenuated vaccine, it should not be given to immunocompromised persons, including those infected with HIV. Antimicrobial medications should be avoided during the week prior to administration of the first dose and for the week after the fourth dose of Ty21a. Administration of proguanil hydrochloride should be delayed until 10 or more days after the fourth dose of Ty21a.

#### Vi Capsular Polysaccharide Vaccine

Immunization may be given to people 2 years of age and older and consists of a single 0.5-mL (25- $\mu$ g) dose administered intramuscularly. The vaccine manufacturer recommends that a booster dose be given every 2 years for continued or renewed exposure to *S. Typhi*.

## Adverse Reactions

Adverse reactions to Ty21a are minimal. These may include abdominal discomfort, nausea, vomiting, fever, headache, rash, or urticaria. Adverse reactions to the ViCPS vaccine are also minimal: fever (0%–1%), headache (1.5%–3%), and local reactions of erythema of induration of 1 cm or greater (7%) have been reported.

## Recommendations for Children under 2 Years of Age and for Pregnant Women

There are no available data concerning the efficacy of either of the licensed vaccines for use in children under 2 years of age. Evidence exists to suggest that breastfeeding and careful preparation of formula may reduce the risk of infection in endemic regions.<sup>109</sup> No safety data are available for the use of typhoid vaccines in pregnant women.

## Nontyphoidal Salmonellosis

DAVID A. PEGUES  
MICHAEL E. OHL  
SAMUEL I. MILLER

### INTRODUCTION

Nontyphoidal *Salmonella* species have been isolated from most animals, including domestic and wild mammals, reptiles, and birds, and are a major source of foodborne disease throughout the developed and developing world.<sup>1</sup> *Salmonella* is readily transmitted to humans by contaminated food or poor sanitation. Infection most often results in self-limited acute gastroenteritis; less frequently, bacteremia with or without focal infection occurs. The widespread distribution of *Salmonella* in the environment; its increasing prevalence in the global food chain; and its virulence and adaptability have an enormous medical, public health, and economic impact worldwide.

### AGENT

*Salmonella* is a genus of the family of Enterobacteriaceae. Like other members of the family, the organisms are gram-negative non-spore-forming facultatively anaerobic bacilli that measure 2 to 3 by 0.4 to 0.6 microns in size.<sup>2</sup> The genome sequences of *Salmonella typhimurium* strain LT2 consists of 4,857,432 base pairs and 5599 coding sequences, including 204 pseudogenes.<sup>3</sup> Although the genome is remarkably similar to that of other Enterobacteriaceae, the 8% of genes unique to subtype 1 *Salmonella* may be involved in adaptation to warm-blooded hosts.

The genus *Salmonella* has two species: *Salmonella choleraesuis*, with six subspecies (I, II, IIIa, IIIb, IV, and VI), and *Salmonella bongori*, which formerly was subspecies V.<sup>4</sup> *S. choleraesuis* subspecies I contains almost all the serotypes pathogenic for humans. Because *S. choleraesuis* refers to both a species and a serotype, the species designation *Salmonella enterica* has been recommended and widely adopted. According to the current *Salmonella* nomenclature system, the full taxonomic designation *Salmonella enterica* subspecies *enterica* serotype *typhimurium* can be shortened to *Salmonella* serotype *typhimurium* or *Salmonella typhimurium*.

Members of the seven *Salmonella* subspecies can be grouped into one of more than 2400 serotypes (serovars) according to somatic O, surface Vi, and flagellar H antigens and habitats (Table 18-1).<sup>5</sup> For simplicity, most *Salmonella* serotypes are named for the city in which they were defined,

**Table 18-1** *Salmonella* Species, Subspecies, Serotypes, and Their Usual Habitats

<i>Salmonella</i> Species and Subspecies	Serotypes Within Subspecies (No.)	Usual Habitat
<i>S. enterica</i> subsp. <i>enterica</i> (I)	1454	Warm-blooded animals
<i>S. enterica</i> subsp. <i>salmae</i> (II)	489	Cold-blooded animals and the environment*
<i>S. enterica</i> subsp. <i>arizonae</i> (IIIa)	84	Cold-blooded animals and the environment*
<i>S. enterica</i> subsp. <i>diarizonae</i> (IIIb)	324	Cold-blooded animals and the environment*
<i>S. enterica</i> subsp. <i>houtenae</i> (IV)	70	Cold-blooded animals and the environment*

and the serotype is often used as the species designation.<sup>4</sup> Although serotyping of all surface antigens can be used for formal identification, most laboratories perform a few simple agglutination reactions that define specific O-antigen serogroups, designated as groups A, B, C<sub>1</sub>, C<sub>2</sub>, D, and E *Salmonella*.<sup>6</sup>

### EPIDEMIOLOGY

#### Incidence

In many countries the incidence of human *Salmonella* infections has increased markedly, although good population-based surveillance data are mostly lacking. In the United States, the incidence rate of nontyphoidal *Salmonella* infection has doubled in the last two decades, with an estimated 1.4 million cases occurring annually.<sup>7,8</sup> In 2002, the incidence rate of salmonellosis (17.7 per 100,000 population) was highest among 10 potentially foodborne diseases under active surveillance and varied little by geographic region (Fig. 18-1).<sup>9</sup> In 2001, *S. typhimurium*, *S. enteritidis*, and *S. newport* were the three most common serotypes, together accounting for half of all laboratory-confirmed cases of human salmonellosis.<sup>10</sup> Nontyphoidal *Salmonella* causes a small but significant proportion of diarrhea among travelers<sup>11</sup> and among young children in developing countries.<sup>12</sup> The incidence of salmonellosis is highest during the rainy season in tropical climates and during May to October in temperate climates in the Northern hemisphere, coinciding with the peak in foodborne outbreaks.

#### Reservoirs and Transmission to Humans

In humans, nontyphoidal *Salmonella* infections are most often associated with food products and are the most frequently identified agent of foodborne disease outbreaks (Fig. 18-2).<sup>13</sup>

**FIGURE 18-1** Incidence rate per 100,000 population of laboratory-confirmed *Salmonella*, *Campylobacter*, *Shigella*, and *E. coli* O157:H7 infections by selected sites in the United States, Foodborne Diseases Active Surveillance Network, 2002. (From Centers for Disease Control and Prevention. Preliminary FoodNet Data on the Incidence of Foodborne Illnesses—Selected Sites, United States, 2002. MMWR 52:340–343, 2003.)

Food of animal origin, including meat, poultry, eggs, and dairy products, can become contaminated with *Salmonella*.<sup>13</sup> Eating uncooked or inadequately cooked foods cross-contaminated with these products may lead to human infection. In the developed world, acquisition of nontyphoidal salmonellosis most often is associated with consumption of poultry and eggs,<sup>13,14</sup> but a wide range of food vehicles have been implicated in transmission to humans.<sup>13,15</sup> Although foodborne outbreaks predominate, waterborne outbreaks of salmonellosis also have been reported.<sup>16</sup> Salmonellosis associated with exotic pets is a resurgent public health problem, with an estimated 3% to 5% of all cases of salmonellosis in humans associated with exposure to exotic pets, especially reptiles.<sup>15</sup>

### Antimicrobial Resistance

Antimicrobial resistance among human nontyphoidal *Salmonella* isolates is increasing worldwide and is likely due, in part, to the widespread use of antimicrobial agents for the

empirical treatment of febrile syndromes and as growth promoters in animal production.<sup>17,18</sup> High rates of resistance (>50% to 100%) to chloramphenicol, trimethoprim-sulfamethoxazole, and ampicillin have been reported from Africa, Asia, and South America. Multidrug-resistant nontyphoidal *Salmonella* has now emerged in developed countries, including the United States (Table 18-2 and Fig. 18-3).<sup>19</sup> Individuals with resistant *Salmonella* isolates are more likely than those with susceptible ones to have been treated with an antimicrobial agent recently, to have systemic infections, to be hospitalized, and to die of their infection.<sup>19,20</sup>

Of particular concern is the worldwide emergence of a distinct strain of multidrug-resistant *S. typhimurium*, characterized as definitive phage type 104 (DT104), that is resistant to at least five antimicrobials—ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracyclines.<sup>21</sup> The DT104 strain has broad host reservoirs and is difficult to control in domestic livestock, leading to its widespread clonal dissemination among food animals, especially cattle, and humans in Europe,

the United States, Canada, and the Middle and Far East.<sup>21–24</sup> Although no more virulent than susceptible *S. typhimurium* strains, infection with DT104 may be associated with greater morbidity and mortality, likely reflecting inadequate empirical antimicrobial therapy.<sup>25</sup>

Outbreaks and sporadic cases of nontyphoidal *Salmonella* resistant to third-generation cephalosporins have been reported in both developed and developing countries.<sup>26</sup> Resistance to third-generation cephalosporins is conferred by conjugative plasmid-encoded  $\beta$ -lactamases from functional groups 1 (AmpC) and 2 (TEM).<sup>26,27</sup> Recent surveys in the United States found that 5.1% of *Salmonella* isolates from cattle and pigs and 1.6% of isolates from humans were ceftriaxone resistant (MIC  $\geq 16$   $\mu\text{g/mL}$ ).<sup>28</sup> Quinolone-resistant *Salmonella* strains have emerged among human and animals, and resistance is due to mutations of the intracellular targets DNA gyrase (*gyrA* or *gyrB*) or topoisomerase IV, or to overproduction of efflux pumps.<sup>29–31</sup> Emergence of quinolone resistance among human *Salmonella* isolates clearly is linked with the use of fluoroquinolones as growth promoters in food animals.<sup>18,32</sup>

### ***Salmonella enteritidis***

*S. enteritidis* associated with shell eggs emerged in the 1980s as the predominant *Salmonella* serotype and source of foodborne disease in the United States and some other countries.<sup>14,33</sup> Infection of egg-laying and broiler poultry flocks with *S. enteritidis* is widespread, although the mechanism of transmission from farm to farm is not known. Infection localizes to the ovaries and upper oviduct tissue and is transmitted to the forming egg before shell deposition.<sup>34</sup> An estimated 2.3 million of 69 billion shell eggs produced annually in the United States contain *S. enteritidis*.<sup>35</sup> Outbreaks of *S. enteritidis*

infection have been associated with ingestion of uncooked or lightly cooked eggs (e.g., sunny side up), egg-containing food products, and inadequately cooked poultry.<sup>14,36</sup> Although cooking of eggs until all liquid yolk is solidified kills *S. enteritidis*, the use of pasteurized egg products remains the safest alternative for institutions and the general public.

### **International Spread of Salmonellosis**

Changes in food consumption and the rapid growth of international trade in agricultural food products have facilitated the dissemination of new *Salmonella* serotypes associated with fresh fruits and vegetables.<sup>37</sup> Human or animal feces may contaminate the surface of fruits and vegetables and may not be removed by washing. Recent foodborne outbreaks of salmonellosis associated with fresh produce include cantaloupe, tomatoes, unpasteurized orange juice, cilantro, and raw seed sprouts. Soaking seeds in sodium hypochlorite can reduce, but does not eliminate, the risk of sprout-associated illness, and thus immunocompromised persons should not eat sprouts.<sup>38</sup> Manufactured food items also pose an enormous potential hazard of foodborne salmonellosis in developed countries because of their centralized production and wide-scale distribution. Recent outbreaks associated with manufactured food products include ice cream (United States, *S. enteritidis*), pasteurized milk (United States, *S. typhimurium*), powdered milk products and infant formula (Canada and United States, *S. tennessee*), unpasteurized goat milk cheese (France, *S. paratyphi*), and ready-to-eat snacks.

### **Transmission in Hospitals and Other Care Facilities**

Although health care–associated salmonellosis is infrequent, such infections have been associated with substantial morbidity and mortality.<sup>39</sup> Although nosocomial transmission of *Salmonella* from patients to health-care workers has been associated with handling soiled linen, noncompliance with barrier precautions, and fecally incontinent residents,<sup>40</sup> the risk of transmission from health-care workers to patients appears to be low if infection control measures are observed carefully.<sup>41</sup> In contrast, the risk of nosocomial fecal-oral transmission to neonates and infants from acutely or chronically infected family members is high, because of relative gastric achlorhydria and the buffering capacity of ingested breast milk and formula.<sup>42</sup> High-iron infant formulas may further increase the risk of infant salmonellosis compared with breast feeding.<sup>43</sup> Contaminated enteral feeding and crowding also have been associated with nosocomial transmission among pediatric patients.<sup>44</sup> Control of outbreaks in day care centers may be difficult because of the need for frequent diaper changing and the higher rate and longer duration of convalescent carriage in the preschool age group.<sup>45</sup>

The elderly are at increased risk for *Salmonella* bacteremia and extraintestinal infection due to debility, underlying illnesses, and waning immunity. Residents of long-term care facilities may be at particular risk of salmonellosis because many of these institutions have only limited infection control programs.<sup>46</sup> From 1975 through 1987, nontyphoidal *Salmonella* was the most common cause of foodborne outbreaks reported from long-term care facilities in the United States, accounting for 52% of outbreaks and 81% of outbreak-associated deaths.<sup>46</sup>

## DISEASE

### Clinical Manifestations

#### Gastroenteritis

Infection with nontyphoidal *Salmonella* most often results in self-limited acute gastroenteritis that is indistinguishable from that due to many other enteric bacterial pathogens. Within 6 to 48 hours after ingestion of contaminated food or water, nausea, vomiting, and diarrhea occur.<sup>47</sup> In most cases, stools are loose, of moderate volume, and without blood. In rare cases, stool may be watery and of large volume (“cholera-like”) or of small volume associated with tenesmus (“dysentery-like”). Fevers (38°C to 39°C), abdominal cramping, nausea,

vomiting, and chills frequently are reported. Headache, myalgias, and other systemic symptoms also can occur. Microscopic examination of stools shows neutrophils and, less frequently, red blood cells. Infrequently, *Salmonella* can cause a syndrome of pseudoappendicitis or can mimic the intestinal changes of inflammatory bowel disease.<sup>47</sup> Toxic megacolon is a rare but potentially life-threatening complication.<sup>48</sup>

Diarrhea is usually self-limited, typically lasting for 3 to 7 days.<sup>47</sup> Diarrhea that persists for more than 10 days should suggest another diagnosis. If fever is present, it usually resolves within 48 to 72 hours. Occasionally, patients require hospitalization for dehydration, and death occurs infrequently. In the United States, nontyphoidal *Salmonella* infections result in an estimated rate of hospitalization of 2.2 per 1 million population

and 582 deaths per year.<sup>8</sup> A disproportionate number of these deaths occur among the elderly, especially those residing in long-term care facilities, and among immunocompromised patients.<sup>14,46,49,50</sup>

After resolution of gastroenteritis, the mean duration of carriage of nontyphoidal *Salmonella* in the stool is 4 to 5 weeks and varies by *Salmonella* serotype.<sup>45</sup> Antimicrobial therapy may increase the duration of carriage.<sup>45</sup> In addition, a higher proportion of neonates have prolonged carriage; in one study, 50% of neonates were still excreting *Salmonella* at 6 months.<sup>51</sup> However, the delayed clearance of infection in neonates does not result in permanent carriage, as almost all chronic carriers are adults.<sup>45,51</sup>

## Bacteremia

Classically, *S. choleraesuis* and *S. dublin* produce a syndrome of sustained bacteremia with fever, but any *Salmonella* serotype can cause bacteremia.<sup>47</sup> From 1% to 4% of immunocompetent individuals with *Salmonella* gastroenteritis have positive blood cultures.<sup>45</sup> The proportion is greater for infants, the elderly, and the immunocompromised, including those with acquired immunodeficiency syndrome (AIDS).<sup>50,52–56</sup> *Salmonella* has a propensity for infection of vascular sites, and high-grade or persistent bacteremia suggests an endovascular infection.<sup>57</sup> The risk of endovascular infection complicating *Salmonella* bacteremia is estimated to be 10% to 25% in persons over 50 years of age, usually involves the aorta, and most commonly results from seeding atherosclerotic plaques or aneurysms.<sup>58,59</sup> Mortality rates range from 14% to 60% and are lower with prompt diagnosis and combined medical and surgical therapy.<sup>60,61</sup>

## Salmonellosis and HIV Infection

HIV-infected individuals have up to a 20- to 100-fold increased risk of salmonellosis compared with the general population.<sup>50</sup> *Salmonella* is more likely to cause severe invasive disease in persons with AIDS compared with infection in immunocompetent persons and those with AIDS-related complex or asymptomatic HIV infection, including fulminant diarrhea, acute enterocolitis, rectal ulceration, recurrent bacteremia, meningitis, and death despite antimicrobial therapy.<sup>62,63</sup> In studies among HIV-infected persons in Africa, *Salmonella* species were one of the most frequent cause of bacteremia, were often multidrug resistant, and were associated with high mortality (24% to 80%) and recurrence rates (43%).<sup>64,65</sup> Focal infections due to nontyphoidal *Salmonella* are infrequent among HIV-infected individuals, most often occurring among those with CD4 counts below 100/mm<sup>3</sup>.<sup>63</sup>

Recurrent nontyphoidal *Salmonella* bacteremia is an AIDS-defining illness that apparently results from incomplete clearance of the primary infection owing to impaired cell-mediated immunity. Without maintenance antimicrobial therapy, up to 45% of individuals with HIV infection will have recurrent bacteremia.<sup>62</sup> Among those with HIV, the incidence of recurrent nontyphoidal *Salmonella* bacteremia has declined, likely owing to the direct bactericidal activity of antiretrovirals on *Salmonella* species, the impact of HAART on immune reconstitution, and the use of trimethoprim-sulfamethoxazole for the prevention of *Pneumocystis* pneumonia.<sup>62,66,67</sup>

## Localized Infections

Localized infections develop in approximately 5% to 10% of persons with *Salmonella* bacteremia, and the presentation may be delayed.<sup>68</sup> Extraintestinal complications of salmonellosis and their management are summarized in Table 18-3.

## Chronic Carrier State

The chronic carrier state is defined as the persistence of *Salmonella* in stool or urine for periods longer than 1 year. From 0.2% to 0.6% of patients with nontyphoidal salmonellosis develop chronic carriage,<sup>69</sup> a lower frequency than that observed in *S. typhi* infection.<sup>58,70,71</sup> The frequency of chronic carriage is higher in women, in persons with biliary abnormalities or concurrent bladder infection with *Schistosoma haematobium*, and in infants.<sup>55,72</sup>

## PATHOGENESIS AND IMMUNITY

### Interactions with Gastrointestinal Tract and Induction of Enteritis

*Salmonella* infections begin with the ingestion of bacteria in contaminated food or water. Investigations of point source outbreaks suggest that as few as 10<sup>3</sup> bacteria may produce nontyphoidal gastroenteritis in many of those exposed and that the ingested dose is an important determinant of incubation period and disease severity.<sup>73</sup> Gastric acidity represents the initial barrier to *Salmonella* colonization, and conditions that increase gastric pH significantly increase susceptibility to infection.<sup>74</sup>

After passage to the small intestine, salmonellae must evade host antimicrobial factors secreted into the intestinal lumen, including antimicrobial peptides, bile salts, and secretory IgA, and traverse a protective mucous barrier before encountering intestinal epithelial cells.<sup>75,76</sup> Salmonellae express multiple fimbriae that contribute to tight adherence to intestinal epithelial cells in culture and are required for colonization in animal models.<sup>77</sup>

Microscopy reveals that salmonellae invade intestinal epithelial cells by a morphologically distinct process termed bacteria-mediated endocytosis (Fig. 18-4).<sup>78,79</sup> Shortly after bacteria adhere to the apical epithelial surface, profound cytoskeletal rearrangements occur in the host cell, disrupting the normal epithelial brush border and inducing formation of membrane ruffles that reach out and enclose adherent bacterial in large vesicles. This process resembles the membrane ruffling induced in many cell types by growth factors and is functionally distinct from receptor-mediated endocytosis, the mechanism by which many other pathogens enter nonphagocytic cells.<sup>80</sup> Following bacterial internalization, a fraction of *Salmonella*-containing vesicles transcytose to the basolateral membrane, and the apical epithelial brush border reconstitutes. The epithelial cell type that serves as the principal portal for *Salmonella* invasion is uncertain. In the mouse enteric fever model, salmonellae preferentially adhere to and enter the specialized microfold cells (M cells) that overlie lymphoid tissue within Peyer's patches.<sup>81</sup> In bovine and rabbit models of enteritis, however, salmonellae do not appear to interact preferentially with M cells but instead adhere to and invade intestinal enterocytes diffusely.<sup>82</sup> It is possible that M cells are the

Table 18-3 Extraintestinal Infectious Complications of Salmonellosis

Site	Incidence	Risk Factors	Manifestations	Complications	Mortality	Diagnosis	Treatment
Endocarditis <sup>58,149</sup>	0.2% to 0.4%	Preexisting valvular heart disease	Valvular vegetation, infected mural thrombus	Valve perforation, relapse (20% to 25%), pericarditis	~70%	Blood culture, echocardiography	Early valve surgery + 6 wk P cep 3,* P amp, <sup>†</sup> P/PO quinolone <sup>‡</sup>

<sup>§</sup>P/PO, parenteral or oral antimicrobial (e.g., quinolone, ampicillin, TMP-SMX, chloramphenicol or third-generation cephalosporin).

**FIGURE 18-4** Scanning electron micrograph showing *Salmonella typhimurium* entering a Hep-2 cell through bacteria-mediated endocytosis. Membrane ruffles extend from the cell surface, enclosing and internalizing adherent bacteria. (Reprinted with permission from Ohl ME, Miller SI: *Salmonella: A model for bacterial pathogenesis*. Annu Rev Med 52:259–274, 2001. ©2001 by Annual Reviews. www.annualreviews.org.)

principal portal of entry in the enteric fever syndrome and that generalized invasion of enterocytes plays a greater role in the enteritis induced by nontyphoidal *Salmonella* serotypes.

*Salmonellae* encode a type III secretion system (TTSS) within pathogenicity island 1 (the SPI-1 TTSS) that is required for bacteria-mediated endocytosis and intestinal epithelial invasion. Type III secretion systems are complex macromolecular machines that have evolved to subvert host cell function through the translocation of virulence proteins directly from the bacterial cytoplasm into the host cell. Two SPI-1 translocated proteins, SipC and SipA, promote membrane ruffling and *Salmonella* invasion through direct interactions with the actin cytoskeleton. The SipC protein inserts into the host cell plasma membrane and directly nucleates actin polymerization at the site of *Salmonella* attachment.<sup>83</sup> The SipA protein further enhances actin polymerization through stabilization of actin filaments and reduction of the critical concentration for polymerization.<sup>84</sup> Additional SPI-1 translocated proteins contribute to *Salmonella* invasion by targeting members of the Rho family of monomeric GTP-binding proteins (G proteins). Rho family members, including cdc42, rac, and rho, regulate the structure and dynamics of the actin cytoskeleton and are required for formation of the membrane ruffles that mediate *Salmonella* internalization. The SPI-1 translocated proteins SopE and SopE2 directly activate rac1

and cdc42 in vitro by acting as GDP/GTP exchange factors (GEFs) and induce membrane ruffling following microinjection into epithelial cells.<sup>85,86</sup> SopB is an additional SPI-1 translocated protein that acts as an inositol polyphosphatase within the host cell.<sup>87</sup> Among other effects, this activity indirectly stimulates Rho GTPases and promotes membrane ruffling.<sup>88</sup> Overall, available data indicate that SipA and SipC act in concert with downstream cellular effectors of activated Rho GTPases to initiate and spatially direct the actin rearrangements that lead to *Salmonella* internalization.

In addition to invasion of intestinal epithelial cells, *Salmonella* serotypes clinically associated with gastroenteritis induce a secretory response in intestinal epithelium and initiate recruitment and transmigration of neutrophils into the intestinal lumen.<sup>89</sup> The SPI-1 TTSS is also required for these responses in tissue culture and animal models of enteritis. Stimulation of Rho GTPase signaling by SopE and SopE2 also leads to activation of MAP kinase pathways and synthesis of proinflammatory cytokines, including the neutrophil chemoattractant IL-8.<sup>86,90</sup> In addition to its role in invasion, the inositol polyphosphatase activity of SopB leads to accumulation of D-myo-inositol-1,4,5,6 tetrakisphosphate in epithelial cells.<sup>91</sup> The increased concentration of this compound ultimately leads to an increase in cellular basal chloride secretion, with associated fluid flux. The SPI-1 translocated proteins SopA and SopD also contribute to intestinal secretory and inflammatory responses in ligated ileal loops, but the molecular basis of these effects remains unclear.<sup>89,92</sup>

Following *Salmonella* invasion, intestinal inflammation may result from activation of the innate immune system through stimulation of proinflammatory receptors present on phagocytes and the basolateral surface of intestinal epithelia. This includes activation of Toll-like receptor 4 (Tlr4) by LPS and Tlr5 by bacterial flagellin.<sup>93,94</sup> Intestinal inflammation probably contributes to fluid secretion and diarrhea through disruption of the epithelial barrier and increased water flux by an exudative mechanism.

*Salmonellae* also utilize the SPI-1 TTSS to deliver proteins that down-regulate the host inflammatory response associated with *Salmonella* invasion. The SptP protein inactivates Rho GTPase signaling by acting as a GTPase-activating protein (Rho GAP).<sup>95</sup> This directly opposes the activity of SopE and SopE2 and reduces membrane ruffling and proinflammatory signaling following bacterial invasion. In addition, the SspH1 and AvrA proteins inhibit NF- $\kappa$ B activation and related host cell cytokine synthesis.<sup>96,97</sup> These SPI-1 translocated proteins may promote bacterial persistence in the host by maintaining host cell integrity and allowing evasion of the host immune response. The presence of SPI-1 translocated proteins with opposing molecular actions (e.g., SopE and SptP) suggests temporal ordering of protein function, with initial activity of SPI-1 proteins associated with invasion and proinflammatory signaling and subsequent activity of anti-inflammatory proteins.

### Interactions with Macrophages and Systemic Infection

*Salmonellae* are facultative intracellular pathogens, and available data from both animal models of infection and humans with enteric fever suggest that bacterial replication within macrophages is essential for production of systemic disease.

The role of intracellular bacterial replication in human gastroenteritis due to nontyphoidal serotypes is less clear, but it is likely that the ability of salmonellae to resist killing by macrophages contributes to the cases of bacteremia and systemic infection occasionally associated with nontyphoidal *Salmonella* infection in humans.

Multiple *Salmonella* regulatory proteins are required for bacterial adaptation to the intracellular environment and replication within macrophages. The PhoP/PhoQ two-component regulatory system senses the intracellular environment and induces transcription of more than 40 *Salmonella* genes required for survival within macrophages.<sup>98</sup> Activation of the PhoP/PhoQ regulon leads to widespread modifications in the protein and lipopolysaccharide components of the bacterial inner and outer membranes.<sup>99,100</sup> These surface modifications confer resistance to antimicrobial factors within the phagosome, including antimicrobial peptides. PhoP/PhoQ regulated lipopolysaccharide modifications include addition of aminoarabinose, ethanolamine, palmitate, and 2-hydroxymyristate to lipid A, thus altering the charge density and fluidity of the outer membrane and discouraging antimicrobial peptide insertion in the membrane.<sup>100,101</sup> In addition, PhoP/PhoQ-regulated modifications in lipid A structure produce a lipopolysaccharide molecule with significantly less proinflammatory signaling activity, which may facilitate bacterial survival within host tissues.<sup>100</sup>

Salmonellae express several enzymes that inactivate microbicidal reactive oxygen and nitrogen species produced within the macrophage. Resistance to nitric oxide (NO) and related reactive nitrogen compounds results in part from bacterial synthesis of homocysteine, an NO antagonist.<sup>102</sup> *Salmonella* mutants unable to synthesize homocysteine due to inactivation of the *metL* gene are hypersensitive to NO and are less virulent. In addition, salmonellae produce at least one superoxide dismutase that inactivates reactive oxygen species.<sup>103</sup>

Recently three laboratories have described a second *Salmonella* type III secretion system that is necessary for survival in the macrophage and establishment of systemic infection.<sup>104–106</sup> Encoded in *Salmonella* pathogenicity island 2 (SPI-2), this system is expressed by intracellular bacteria and translocates proteins across the membrane of the *Salmonella*-containing vacuole (SCV) into the macrophage cytosol.<sup>107</sup> SPI-2 translocated proteins appear to regulate the maturation of the SCV into a mature phagolysosome, thus creating an intracellular compartment favorable for bacterial replication. Several SPI-2 translocated proteins, including SifA, SifB, SseJ, SopD2, PipB, and PipB2 localize to the surface of the SCV and may alter its fusion with other membranous compartments within the macrophage.<sup>108–112</sup> Two additional SPI-2 translocated proteins, SspH2 and SseI, interact with the actin cytoskeleton surrounding the SCV and probably contribute to remodeling of vacuole-associated actin networks.<sup>107</sup> Recent studies indicate that SPI-2 mediated modifications in the SCV lead to exclusion of the NADPH oxidase and inducible nitric oxide synthase from the vacuolar membrane, allowing the bacterium to evade the reactive oxygen and nitrogen species produced by these enzymes.<sup>113,114</sup>

SpvB is a *Salmonella* virulence protein that is secreted into the macrophage cytoplasm, possibly by the SPI-2 TTSS, and ADP-ribosylates monomeric actin (G-actin), thus promoting disassembly of actin networks around the vacuole.<sup>107,115</sup>

SpvB promotes bacterial dissemination beyond the intestine in animals and bacteremia in humans.<sup>116</sup> Other bacterial factors, including incompletely characterized cytotoxin genes and genes required for synthesis of essential nutrients and iron acquisition, also are important in systemic pathogenesis.<sup>117–119</sup>

## Host Response and Immunity

The innate immune system senses invasive *Salmonella* infections using Toll-like receptors that recognize conserved elements of bacterial structure, including recognition of LPS by Tlr4, bacterial lipoproteins by Toll-like receptor 2 (Tlr2), and flagellin by Tlr5.<sup>94</sup> Activation of these receptors on phagocytes and epithelia leads to synthesis of cytokines that orchestrate the acute inflammatory response and instruct the subsequent antigen-specific immune response. Mice lacking a functional Tlr4 response are highly susceptible to *Salmonella* infection, confirming the importance of this initial response to infection.<sup>120</sup> Studies in mice demonstrate that the initial control of *S. typhimurium* replication in host tissue requires recruitment and activation of macrophages.<sup>121</sup> In both mice and humans, macrophage activation and efficient killing of *Salmonella* is associated with production of IFN- $\gamma$ , IL-12, and TNF-1.<sup>122–124</sup> Mice with targeted disruptions in these genes are highly susceptible to infection. In addition, humans with mutations in the IFN- $\gamma$  and IL-12 receptor genes develop severe infections with nontyphoidal *Salmonella* serotypes.<sup>125,126</sup>

Although the innate immune system is able to suppress initial *Salmonella* replication, final clearance of infection and immunity to rechallenge requires a Th1-type CD4 T-cell response and production of specific antibodies by B cells.<sup>124</sup> This is supported by the observation that mice lacking mature CD4 cells (H2I;AB-/- mice) or B cells (Igh-6-/- mice) are unable to control *Salmonella* infection.<sup>124,127,128</sup> The importance of cellular immunity in controlling *Salmonella* infection in humans is demonstrated by the extreme susceptibility of individuals with HIV infection, lymphoproliferative diseases, or immune suppression following transplantation.<sup>50,52,53,62,129</sup>

## DIAGNOSIS

### Isolation and Identification

Freshly passed stool is preferred for the isolation of *Salmonella*. Stool is plated directly onto agar plates. Low-selective media, such as MacConkey agar and deoxycholate agar, and intermediate-selective media, such as *Salmonella-Shigella*, xylose-lysine-deoxycholate, or Hektoen agar, are widely used to screen for both *Salmonella* and *Shigella* species. New selective chromogenic media, such as CHROMagar and COMPASS agar, are more specific than other selective media, reduce the need for confirmatory testing and time to identification, and increasingly are used for the primary isolation and presumptive identification of *Salmonella* from clinical stool specimens.<sup>130</sup>

In addition to plating stool onto primary media, tetrathionate- and selenite-based enrichment broths are often used to facilitate the recovery of low numbers of organisms.<sup>130</sup> Highly *Salmonella*-selective media, such as selenite with brilliant green, should be reserved for use in stool cultures of suspected carriers and for outbreaks. Bismuth sulfite agar, which contains an indicator of hydrogen sulfide production and does

not contain lactose, can be used for the detection of the 1% of *Salmonella* strains (including most *Salmonella* serogroup C strains) that ferment lactose.<sup>131</sup>

After primary isolation, possible *Salmonella* isolates can be tested in commercial identification systems or inoculated into screening media such as triple sugar iron and lysine iron agar. Rapid, IgM antibody-based serologic tests have been developed and may supplement stool culture for the diagnosis of acute *Salmonella* infection.<sup>132</sup> Isolates with typical biochemical profiles for *Salmonella* should be serogrouped with commercially available polyvalent antisera or sent to a reference or public health laboratory for complete serogrouping.

## Molecular Typing

Subtyping methods frequently are used for epidemiologic purposes to differentiate strains of common *Salmonella* serotypes. Phenotyping methods may be useful for characterizing outbreak-associated strains and sporadic multidrug-resistant isolates, and include bacteriophage typing, plasmid profile analysis, antimicrobial susceptibility, and biotyping. More discriminative genotyping techniques, including ribotyping, pulsed-field gel electrophoresis, insertion sequences analysis, PCR-based fingerprinting, and multilocus sequence typing, have been used in epidemiologic studies to differentiate strains within a given serotype. Genomic DNA analysis using microarrays may complement the other genotyping methods.<sup>133</sup> However, lack of standardization and time requirement limit the widespread use of these genotyping techniques.

## TREATMENT

### Gastroenteritis

*Salmonella* gastroenteritis is usually a self-limited disease, and therapy primarily should be directed to the replacement of fluid and electrolyte losses. In a large meta-analysis, antimicrobial therapy for uncomplicated nontyphoidal *Salmonella* gastroenteritis, including short-course or single-dose regimens with oral fluoroquinolones, amoxicillin, or trimethoprim-sulfamethoxazole, did not significantly decrease the length of illness, including duration of fever or diarrhea, and was associated with an increased risk of relapse, positive culture after 3 weeks, and adverse drug reactions.<sup>134</sup> Therefore, antimicrobials should not be used routinely to treat uncomplicated nontyphoidal *Salmonella* gastroenteritis or to reduce convalescent stool excretion.

Although less than 5% of all patients with *Salmonella* gastroenteritis develop bacteremia, certain individuals are at increased risk for invasive infection and may benefit from pre-emptive antimicrobial therapy. Antimicrobial therapy should be considered for neonates, persons older than 50 years, and those with immunosuppression or cardiac valvular or endovascular abnormalities, including prosthetic vascular grafts. Treatment consists of an oral or intravenous antimicrobial administered for 48 to 72 hours or until the patient becomes afebrile. Longer treatment may result in a higher rate of chronic carriage and relapse. For susceptible organisms, treatment with an oral fluoroquinolone, trimethoprim-sulfamethoxazole, or amoxicillin is adequate. Occasionally, antimicrobial prophylaxis has been required to control institutional outbreaks,

particularly in long-term care facilities and pediatrics wards, where compliance with infection control measures may be difficult.<sup>135</sup>

Although fluoroquinolones are not recommended for administration to children less than 10 years of age, they may have a role in treating severe nontyphoidal salmonellosis in this age group. In a small study, seven children with severe typhoidal or nontyphoidal salmonellosis who did not improve on conventional therapy improved rapidly when treated with oral perfloracin (12 mg/kg daily for 7 days).<sup>136</sup> In addition, a double-blind placebo-controlled trial in Turkey demonstrated that intravenous immunoglobulin (500 mg/kg on days 1, 2, 3, and 8) in combination with cefoperazone when administered to preterm neonates with *S. typhimurium* infection reduced the rate of mortality, complications, and duration of antimicrobial therapy compared with treatment with cefoperazone alone, a finding that merits further study.<sup>137</sup>

### Bacteremia

Because of the increasing prevalence of antimicrobial resistance, empirical therapy for life-threatening bacteremia or focal infection suspected to be caused by nontyphoidal *Salmonella* should include a third-generation cephalosporin and a fluoroquinolone until susceptibilities are known. It is also important to document whether the bacteremia is high grade (i.e., >50% of three or more blood cultures are positive) and, if so, to search for endovascular abnormalities by echocardiogram or other imaging techniques, such as CT or indium-labeled WBC scan. Low-grade bacteremia not involving vascular structures should be treated with intravenous antimicrobial therapy for 7 to 14 days. Six weeks of intravenous therapy with a  $\beta$ -lactam antibiotic, such as ampicillin or ceftriaxone, is recommended to treat documented or suspected endovascular infection. Intravenous ciprofloxacin followed by prolonged oral therapy may be an option, but published clinical experience is limited.<sup>61</sup> Chloramphenicol should not be used to treat endovascular infection because of high failure rates.<sup>57,138</sup> In addition, early surgical resection of infected aneurysms or other infected endovascular sites is recommended.<sup>60,61</sup> Patients with infected prosthetic vascular grafts that could not be resected have been maintained successfully on chronic suppressive oral therapy.<sup>139</sup>

### Recurrent *Salmonella* Bacteremia in Individuals with AIDS

In persons with AIDS and a first episode of *Salmonella* bacteremia, 1 to 2 weeks of intravenous antimicrobial therapy followed by 4 weeks of oral fluoroquinolone therapy (e.g., ciprofloxacin 500 to 750 mg twice daily) should be administered to attempt eradication of the organism and to decrease the risk of recurrent bacteremia.<sup>140</sup> Persons who relapse following 6 weeks of antimicrobial therapy should receive long-term suppressive therapy with an oral fluoroquinolone or trimethoprim-sulfamethoxazole. Fluoroquinolones and zidovudine have a synergistic antibacterial effect against *Salmonella*; administration of both drugs may dramatically decrease the risk of recurrent infection.<sup>141</sup> Although data are lacking, trimethoprim-sulfamethoxazole may be a good choice for long-term suppressive therapy of salmonellosis if the

organism is susceptible because of its efficacy in prevention of other opportunistic infections, including *Pneumocystis pneumonia*.

### Chronic Carrier State

Chronic carriage of nontyphoidal *Salmonella* is managed similarly to typhoid carriage. Amoxicillin (3 g for adults or 100 mg/kg for children divided three times a day for 3 months), trimethoprim-sulfamethoxazole (one double-strength tablet twice a day for 3 months), and ciprofloxacin (750 mg twice daily for 4 weeks) are effective in eradication of chronic carriage associated with susceptible strains, with cure rates of more than 80%.<sup>142,143</sup> The high concentration of amoxicillin and fluoroquinolones in bile and the superior intracellular penetration of fluoroquinolones are theoretical advantages over trimethoprim-sulfamethoxazole. Cost considerations favor the use of amoxicillin for treating carriage of susceptible organisms. However, antimicrobial agents are infrequently effective in eradicating the carrier state if anatomic abnormalities, such as biliary or kidney stones, are present. In such cases, surgery combined with antimicrobial therapy often is required for eradication.<sup>69</sup> Chronic suppressive antimicrobial therapy should be considered for those patients with persistent carriage in whom no anatomic abnormality can be identified or who relapse after cholecystectomy.

### PREVENTION AND CONTROL

The prevention and control of salmonellosis require both an understanding of the complex cycles of transmission and ongoing surveillance to characterize trends in *Salmonella* occurrence and to identify outbreaks. Control of foodborne salmonellosis requires barriers to the introduction and multiplication of *Salmonella* from the farm to the table.<sup>144</sup> Recognition of foodborne outbreaks requires that clinicians have a high index of suspicion, order the appropriate laboratory test, and promptly report positive culture results to local public health departments. Vaccination of feed animals, limiting the use of antimicrobials as growth promoters, and improved food safety practices should further reduce the burden of foodborne salmonellosis. The use of algorithms and rapid molecular subtyping have improved the ability to detect clusters and outbreaks of salmonellosis.<sup>145</sup> Establishment of cooperative international surveillance systems has facilitated rapid data exchange for the prevention of human salmonellosis associated with the widely distributed agricultural and manufactured foods.<sup>146,147</sup>

Although most cases of *Salmonella* infection occur sporadically, large numbers of persons potentially may become infected when commercial kitchens serve *Salmonella*-contaminated foods that have been insufficiently cooked or mishandled. Commercial food service establishments can reduce the risk of foodborne *Salmonella* illness by not serving food containing raw or undercooked eggs, by using pasteurized eggs whenever possible, and by avoiding cross-contamination of food items. Use of pasteurized eggs for all recipes calling for bulk pooled eggs is recommended for all long-term care facilities and hospitals.<sup>46</sup>

The most cost-effective approach to the control of salmonellosis in food handlers is attention to good personal hygiene

and maintenance of time-temperature standards for food handling. Routine screening of food handlers for carriage after gastroenteritis is common before allowing individuals to return to work. However, there seems to be little justification for this approach, since few outbreaks are related to specific food handlers, prolonged carriage in food handlers after gastroenteritis is rare, and the number of organisms present is small. Therefore, it is reasonable to allow individuals to return to work after diarrhea is resolved. Two consecutive negative stool samples should be required only for food handlers whose work involves touching unwrapped foods that are consumed raw or served without further cooking. Routine surveillance of food handlers for asymptomatic stool carriage of *Salmonella* is not recommended.

To limit the risk of nosocomial transmission to patients and health-care workers, patients excreting *Salmonella* should be managed with Standard Precautions, including the use of barrier precautions, such as gloves, when performing direct patient care or handling soiled articles. Control of *Salmonella* outbreaks in long-term care facilities or neonatal care areas may be difficult because of poor compliance with isolation precautions and the increased susceptibility of these patients.<sup>148</sup> Although *Salmonella* infection in newborns, the elderly, or immunocompromised can be severe, the risk of transmission of *Salmonella* from health-care workers to patients appears to be very small.<sup>41</sup> Once health-care workers are asymptomatic and passing formed stool, they should be allowed to return to work if Standard Precautions are observed. However, local and state regulations should be followed, since some require work exclusion for health-care workers with salmonellosis until two or more stool cultures obtained at least 24 hours apart are negative.

# Shigellosis

GERALD T. KEUSCH  
DENNIS J. KOPECKO

## INTRODUCTION

Shigellosis, a disease typically associated with poverty, poor hygiene, and crowded living conditions, remains a common cause of diarrhea, dysentery, and death in developing countries as well as an important contributor to childhood malnutrition.<sup>1</sup> In 1999, the estimated global mortality due to shigellosis was 1.1 million, with 99% of the deaths occurring in the developing world.<sup>2</sup> In such settings, *Shigella* spp. cause 5% to 15% of all diarrhea cases and the majority of bloody diarrhea or dysentery episodes in infants and children seeking care in clinics or hospitals. In contrast, in the United States, *Shigella* accounts for less than 1% of documented intestinal infections. Moreover, most patients have mild-to-moderate watery diarrhea indistinguishable from that due to other causes such as rotavirus; therefore, the diarrhea is not investigated microbiologically and thus goes unreported. The Centers for Disease Control and Prevention (CDC) recently estimated that there are more than 440,000 cases of shigellosis annually in the United States,<sup>3</sup> although the number of documented cases is in the range of 10,000 to 20,000 per year. For reasons that are not well understood, transmission of the most virulent serotype, *Shigella dysenteriae* type 1, occurs almost exclusively in developing countries.<sup>4</sup> This organism is responsible for large-scale, often devastating epidemics, now often in settings of humanitarian emergencies with large numbers of refugees, such as the 1994 outbreak among Rwandan refugees, killing an estimated 30,000 people in just a few weeks.<sup>5</sup> In wealthier countries, *Shigella sonnei*, the least virulent *Shigella* species, is the most prevalent, with significant outbreaks occurring among the increasing number of young children in day-care centers, where inadequate hygienic conditions facilitate person-to-person spread of infection.<sup>3</sup>

## AGENT

Dysentery has been a well-characterized syndrome since antiquity. However, it was just over a century ago, during a severe outbreak in Japan, that the first complete description of the prototypic *Shigella* species was accomplished by Kiyoshi Shiga,<sup>6</sup> for whom the organism was ultimately named. Dysentery, the prototypic classic presentation of shigellosis, consists of a triad of findings, including the frequent passage of small-volume bloody stools, abdominal cramps, and tenesmus (the painful straining to pass stool), and is often referred to as bacillary dysentery to distinguish it from

amebic dysentery, the other major cause of the syndrome in the tropics, caused by the protozoan *Entamoeba histolytica*.

*Shigella*, a gram-negative rod-shaped organism that grows aerobically and anaerobically, is a highly host-adapted member of the family Enterobacteriaceae that naturally infects humans and nonhuman primates such as gibbons, gorillas, and rhesus monkeys.<sup>7</sup> It cannot be differentiated from *Escherichia coli* by contemporary criteria of DNA relatedness, and were it discovered today it would be classified within the genus *Escherichia*.<sup>8</sup> While genetic analysis indicates that the different *shigella* serotypes evolved from various *E. coli* serotypes, *Shigella* has remained a separate genus because of its historic separation and distinctive clinical illnesses. Unlike most *E. coli* and *Salmonella* strains, *Shigella* does not possess flagella and is nonmotile. There are a number of biochemical differences between *Shigella* and other Enterobacteriaceae, but these are of no particular importance for diagnosis or, apparently, for virulence.

The original isolate described by Shiga is now known as *S. dysenteriae* serotype 1. At least 11 additional serotypes of this species have been described, and new putative strains continue to be reported. Over the 4 decades following the original description of the prototype organism, three additional *Shigella* species, most containing a number of serotypes, subtypes, or phage (or colicin) types, were described.<sup>1</sup> These include, in decreasing order of the severity of illness they cause, *S. flexneri*, *S. boydii*, and *S. sonnei*. Although *S. dysenteriae* can be readily distinguished from the other three species by its inability to ferment mannitol, in practice the four species are identified primarily by their inability to utilize lactose or produce H<sub>2</sub>S, and then distinguished by serologic characteristics.

## EPIDEMIOLOGY

*Shigella* are present wherever humans exist. Direct spread from one person to another is a major route of transmission, facilitated by the very low inoculum of organisms required for infection. For example, experimental human studies have shown that just 10 to 100 *S. dysenteriae* 1 will cause infection in many and clinical disease in 10% to 20% of nonimmune subjects.<sup>9</sup> Transmission is fecal-oral, generally secondary to initial contamination of the hands with infected feces. Failure to hand wash results in the transfer of organisms directly to the mouth or to an inanimate object subsequently handled by another susceptible person. *Shigella* may also be transferred from feces or via contaminated hands to food or water, allowing the organisms to multiply and cause common-source outbreaks. Fly species attracted to human feces can also serve this transfer role to food or water, especially where sanitary facilities are poor. In such settings, the use of traps to reduce the fly population is reported to diminish the incidence of shigellosis.<sup>10</sup> The organisms have also been transmitted sexually, via anal-oral contact. These multiple routes promote the efficient transmission of *Shigella* infection, even though the genus is not hardy outside the human intestinal tract. Because environmental and major animal reservoirs do not exist, it is theoretically possible to control the incidence of infection by effective environmental sanitation of fecal waste.

The incidence of shigellosis is highest in children 1 to 5 years of age, presumably because good personal hygiene is more difficult to achieve in the young and because they have not yet acquired specific immunity. In many disease-endemic countries *Shigella* infections peak during the hot

■ *Shigella dysenteriae* type 1, major areas of endemicity

dry season, when water for hand washing and washing food and cooking utensils can be in short supply. In some countries, however, peaks occur in the rainy season, as the rains wash contaminated feces from the environment into drinking water sources. In the United States, shigellosis is common in infant day-care centers, where nonimmune young children cluster and good hygiene is difficult to maintain. Similar conditions on reservations for native Americans also place them at high risk for shigellosis.

Even though the organisms are present worldwide, the distribution of the four *Shigella* species is closely related to social and economic development. Although the explanation is uncertain, *S. dysenteriae* type 1 diminished in prevalence and then virtually disappeared as a cause of clinical disease following World War I, and was replaced by *S. flexneri* spp. Following World War II, however, *S. flexneri* was progressively replaced in industrialized countries by *S. sonnei* while remaining the predominant isolate in developing countries. Again the reason is unclear; however, it has been hypothesized that contamination of water in developing countries with *Plesiomonas shigelloides*, which can express the same O antigen as *S. sonnei*, induces a common O-antigen-specific immunity.<sup>11</sup> Perhaps signaling its evolutionary origins, the fourth species, *S. boydii*, is present primarily in the Indian subcontinent and has always been an uncommon isolate elsewhere.

*S. dysenteriae* type 1, the only epidemic member of the genus, re-emerged in 1969 in a major outbreak in Mexico and Central America, resulting in several hundred thousand deaths. Subsequent epidemics in South Asia and Africa signaled the return of this organism to prominence throughout the developing world.<sup>1</sup>

## DISEASE

Symptoms of shigellosis typically begin 24 to 72 hours after ingestion of the organism, with malaise and fever, followed shortly by diarrhea, usually watery at the outset. This may evolve into bloody diarrhea or the prototypical manifestation of *Shigella* infection, dysentery, which is characterized by the frequent passage of small volume, grossly bloody and mucoid stools (Fig. 19-1), accompanied by tenesmus, which

**FIGURE 19-1** Typical dysenteric stool, a small-volume 5- to 10-mL stool containing bloody fluid and mucus. Such stools may be passed 30 or more times per day.

is painful straining at defecation. These manifestations result from inflammation and ulceration of the colonic mucosa and an intense proctitis. Dysentery is not an invariable consequence of *Shigella* infection, and is in large part determined by the identity and virulence of the infecting strain. Thus, most patients with *S. sonnei* infections never develop dysentery, whereas the reverse is true for *S. dysenteriae* type 1 infection.

*Shigella* dysentery is associated with profound anorexia.<sup>12</sup> Because the stomach and small bowel are not involved in shigellosis, neither vomiting nor severe dehydration are prominent manifestations, although mild-to-moderate dehydration may occur as a result of stool water losses, increased insensible water loss from fever, and reduced food and fluid intake. In contrast, the intensity of the proctitis can be so severe that rectal prolapse occurs, especially in small children with *S. dysenteriae* type 1 or *S. flexneri* infection.<sup>13</sup> Functional intestinal obstruction and toxic megacolon is another complication due to severe inflammation (Fig. 19-2), most commonly with *S. dysenteriae* type 1 infection.<sup>14</sup> Although infection with *Shigella* usually does not progress beyond the lamina propria, colonic or distal ileal perforation is a rare complication, occurring most typically in neonates or malnourished children.<sup>15</sup> Bacteremia due to the infecting *Shigella* organism itself or other Enterobacteriaceae may

be present, usually in malnourished or immunocompromised patients.<sup>16</sup>

Shigellosis is associated with a number of systemic complications. Generalized motor seizures can be the presenting feature of disease in some patients, especially young children with high fever.<sup>17</sup> The seizures appear to be more common with *S. sonnei* and are rarely recurrent. Patients with shigellosis may become profoundly obtunded or even comatose, usually in association with metabolic aberrations such as severe hypoglycemia and hyponatremia.<sup>18</sup> Hypoglycemia occurs in the face of starvation and an inadequate gluconeogenic response and may be profound ( $< 1$  mmol/L). Hyponatremia is associated with dysenteric forms of shigellosis, and in Bangladesh serum sodium concentrations less than 125 mmol/L are present in approximately 50% of all patients with severe *S. dysenteriae* type 1 and 25% of those with *S. flexneri* infection. This is due to sodium loss in the stool plus secretion of antidiuretic hormone in amounts inappropriate for the serum sodium concentration, possibly triggered by the profound hypoalbuminemia and decreased intravascular oncotic pressure found in many patients with severe dysentery.<sup>19</sup>

The most dramatic systemic complication of shigellosis is hemolytic-uremic syndrome (HUS), a thrombotic microangiopathy characterized by hemolytic anemia, thrombocytopenia, and oliguric renal failure. It occurs in *S. dysenteriae* type 1 infection, usually first noted 1 to 5 days after the appearance of the dysentery, often as the intestinal disease is subsiding.<sup>19</sup> Both the renal failure and the hemolytic anemia can be severe, whereas the thrombocytopenia is usually less so, with platelet counts in the range of 25,000 to 100,000/mm<sup>3</sup> and without bleeding manifestations except in the gut. HUS is often incomplete; each of the three findings can occur in isolation.<sup>20</sup> Shigellosis can also have a profound effect on nutrition in children, and wherever shigellosis is hyperendemic, as in Bangladesh, it is a major contributor to the high prevalence of malnutrition for two main reasons:

1. Patients with shigellosis have increased energy requirements owing to the effects of fever (see Chapter 5).<sup>21</sup>
2. The metabolic consequences of the inflammatory cytokines released in the host response result in muscle protein catabolism, altered priorities for protein synthesis, and decreased nutrient intake because of anorexia.

In addition, these patients lose considerable amounts of protein in the gut owing to epithelial cell death, ulceration, and the transudation of serum into the colonic lumen,<sup>22</sup> which exacerbates the negative nitrogen balance induced by the infection. In developing countries, the more severe *Shigella* infections due to *S. dysenteriae* type 1 and *S. flexneri* almost double the subsequent rate of persistent ( $> 14$  days) diarrhea and increase mortality by 10-fold.<sup>23</sup>

## PATHOGENESIS AND IMMUNITY

As they exit the infected host in stool, shigellae are acid resistant. This is the consequence of growth phase-regulated activation of a glutamate-dependent acid-resistance system,<sup>24</sup> transcriptionally regulated by the alternative sigma factor RpoS of RNA polymerase, which is induced only during the stationary phase of the growth cycle.<sup>1,25</sup> This property allows

**FIGURE 19-2** Bangladeshi child with toxic megacolon caused by *Shigella dysenteriae* type 1 infection. The dilated loops of bowel are clearly outlined on the abdominal wall.

the organisms to tolerate exposure to pH below 2.5 for several hours. This facilitates their survival during passage through the acidic environment of the stomach and accounts in large part for the low oral infectious dose of *Shigella*. Stationary-phase growth occurs when shigellae are present in the distal colon, endowing them with a property as they are about to be excreted in feces that increases the likelihood that they will successfully colonize the next susceptible host they encounter. Once past the stomach shigellae invade host cells of the terminal ileum and colon and multiply within the cytoplasm, sequestered from extracellular host defenses. This efficient host cell invasion ability also contributes to the low inoculum required for infection by these organisms. Interestingly, organisms in the acid-resistant state do not efficiently invade mammalian cells, and once past the stomach, shigellae downregulate acid-resistance genes and transcriptionally upregulate invasion genes. Invasion of the intestinal epithelium proceeds by means of a complex mechanism mediated by both microbial and host proteins.<sup>2,26,27</sup> Intimate biochemical “cross-talk” signals between *Shigella* and various host cell types activate specific bacterial genes necessary for virulence. These include the type 3 secretion system and invasion mediators and leads to essential host cell responses, such as cytoskeletal actin rearrangements and inflammation.<sup>3</sup>

Our understanding of the invasion process and the ensuing host-mediated pathogenesis of disease has undergone dramatic extensions in the past decade as a result of both new cell biology studies and revolutionary findings of pathogen-recognition receptors for innate immunostimulation.<sup>28</sup> On the basis of the results of early molecular genetic studies of *Shigella*, combined with tissue culture invasion assays, *Shigella* was thought simply to employ a set of genes encoded on a large 180- to 220-kb plasmid, termed *ipaB*, *ipaC*, and *ipaD* (for invasion plasmid antigens) to induce bacterial uptake by a phagocytosis-like process at the luminal surface of intestinal mucosal cells. Following ingestion, the organisms reached the cytoplasm within a host cell membrane-bound endosome (Fig. 19-3).<sup>29</sup> Subsequent lysis of the endosome membrane released bacteria into the cell cytoplasm, where they multiplied, leading ultimately to death of the host cell. It seemed reasonable to presume that pathogen-induced host mucosal cell death was responsible for the colitis that characterizes dysentery. New information dramatically changed the paradigm of *Shigella* pathogenesis, and the pathologic consequences of shigellosis are now thought to be due largely to an imbalanced inflammatory over-response to the pathogen that results in formidable local intestinal tissue damage.

The mucus-covered epithelium constitutes a major line of defense against most enteric microbes because they cannot cross this tight epithelial cell monolayer barrier. In addition, it is endowed with both intracellular and extracellular receptors to recognize microbial invasion and activate the innate immune system.<sup>15</sup> Because *Shigella* requires mucosal invasion to cause disease, it has developed unique molecular strategies to breach the mucosal barrier. Convincing evidence now exists that shigellae initially traverse the mucosa, not through epithelial cells as originally believed, but rather through M cells, specialized for antigen processing.<sup>30</sup> Organisms thus reach the underlying lymphoid follicles, apparently without disrupting the M cells, and encounter and are phagocytosed by resident macrophages. Following lysis of the

**FIGURE 19-3** Invasion of cultured HeLa cell monolayers by *Shigella flexneri*. The bacterial cell at the top of the figure has initiated the reorganization of the epithelial cell cytoskeleton, and the actin-based movement of the host cell membranes to form a phagocytic vacuole is evident. The two pseudopods of host cell origin will fuse at the top, engulfing the bacterium within a membrane-bound endosome. An organism within an endosome is present at the lower portion of the photomicrograph (arrowhead).

phagosomal vacuole, shigellae are released into the cytoplasm, where they multiply, leading to apoptosis, or programmed cell death, of infected macrophages.<sup>31</sup> This process is triggered by caspase 1, activated by the *ipaB* gene product,<sup>32</sup> a critical bacterial virulence factor involved in invasion as well. With macrophage death, intracellular stores of the mature inflammatory cytokines interleukin-1 $\beta$  (IL-1 $\beta$ ) and IL-18 are released.<sup>33</sup> In addition, as demonstrated by infection of differentiated intestinal epithelial cell monolayers in culture, invasive organisms such as *Shigella*, but not noninvasive organisms such as normal flora *E. coli*, result in the toll-like receptor (TLR)-4-mediated upregulation of proinflammatory cytokine genes<sup>16</sup> and an increase in epithelial cell secretion of cytokines such as IL-8 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).<sup>34</sup> Studies of rectal samples from acutely ill or convalescing shigellosis patients show a pattern of IL-1, IL-4, IL-6, IL-8, TNF- $\alpha$ , and gamma interferon (IFN- $\gamma$ ) production; severe illness is associated with markedly increased IL-1 $\beta$ , IL-6, TNF- $\alpha$ , and IFN- $\gamma$  expression.<sup>14</sup> IL-1 $\beta$  and IL-8 both induce the migration and activation of polymorphonuclear neutrophils (PMNs), resulting in the local recruitment of PMNs to the lamina propria, in preparation for their transmigration between the epithelial cells to the gut lumen.<sup>35</sup>

*Shigella* lipopolysaccharide (LPS) is a critical signal for PMN adherence and migration. The LPS is translocated in an active form from the luminal (apical) to the mucosal (basal) side of intestinal epithelial cells, where it interacts with circulating host LPS-binding protein and is then recognized by the PMN ligand, CD14. This sequence of events leads to upregulation and activation of the PMN adherence ligand CD11b/CD18, which is required for transepithelial migration.<sup>36</sup> Other yet uncharacterized *Shigella* factors apparently mediate the migration of PMNs between the epithelial cells (paracellular pathway), which disrupts the integrity of the tight junctions and allows *Shigella* and other luminal bacteria to breach the mucosal epithelium in large numbers. Their access to the basolateral epithelial surface triggers the pathogen recognition TLRs, leading to further upregulation of proinflammatory cytokines.<sup>16</sup>

Thus, invasion of the epithelial mucosa actually involves three processes: a primary translocation across the mucosa via M cells, a secondary invasion process in which the bacteria released from dead macrophages or translocated across the mucosa invade the basolateral surface of the mucosa, and a tertiary amplification of epithelial cell invasion when the tight junction is disrupted and organisms invade through the damaged barrier. All three are essential to disease pathogenesis. In the rabbit model, for example, if the action of IL-1 is blocked by pretreatment with IL-1 receptor antagonist,<sup>37</sup> or if neutrophil chemotaxis and migration are prevented by antibody to PMN surface determinants essential to this process, for example, anti-CD18,<sup>23</sup> the progression of the infection is halted and no clinical disease ensues. *Shigella*, long believed to be directly responsible for tissue destruction and the ensuing immune response, which was thought to clear the infection, clearly activates innate immune responses that are both defensive (PMN-mediated killing of shigellae) and offensive (destabilization of epithelial cohesion and mucosal damage). Specifically, *Shigella* infection activates PMNs and triggers degranulation, damaging surrounding tissue,<sup>38</sup> while the organisms are efficiently trapped within and killed by the PMNs via a mechanism that does not require oxygen.<sup>39</sup> The inflammatory response in shigellosis is in reality a double-edged sword,<sup>40</sup> and the resulting innate immune response imbalance to some degree mimics the immunologic over-response seen in inflammatory bowel diseases.<sup>15</sup>

The invasion of intestinal epithelial cells itself is dependent on a microbial needle-like secretion apparatus (termed type III) that injects the effector *ipa* invasins through the host cell membrane into the periplasm to initiate the invasion process into M cells, macrophages, and absorptive epithelial cells.<sup>14</sup> These effectors modulate the activities of Cdc42, Rac, and Rho, which are small GTPases that control actin polymerization and the cellular extensions involved in the macropinocytic uptake of *Shigella*. Lysis of the endosomal membrane proceeds via the actions of IpaB and IpaC, releasing organisms into the cytoplasm. *Shigella* mutants that cannot lyse the endosomal vacuole also cannot multiply and are essentially avirulent. As the bacteria in the cytoplasm multiply, actin filaments are polymerized at one pole of the bacterium and are bundled to form an actin tail.<sup>41</sup> Other host cell proteins also are deposited in the actin tail, including plastin (an actin-binding isoform of fimbrin), vinculin (involved in linking actin bundles to the plasma membrane),

and filamin (an actin gelation protein).<sup>14,42,43</sup> This process is energized by the microbial protein IcsA, an adenosine triphosphatase (ATPase) necessary for actin polymerization.<sup>44</sup> IcsA mutant strains, which fail to generate an actin tail, do not move within the cell and are of reduced virulence. Actin polymerization at the tail end pushes the organism forward, and for this reason it is often referred to as the “actin motor.” The unipolar localization of IcsA, the nucleator of the actin tail, is dependent on normal LPS, inasmuch as LPS mutants show aberrant surface localization of IcsA.<sup>45</sup> The actin motor can drive shigellae to the plasma membrane, where they push out from the surface in long, membrane-bound protrusions (dubbed “fireworks” as studied in nonconfluent cultured cells)<sup>46</sup> (Fig. 19-4). In confluent cells, these protrusions are found in the intermediate junction regions, below the tight junctions, where epithelial cells contact one another, and constitute a unique mechanism for intercellular spread of shigellae.<sup>47</sup> The protrusions indent the membrane of the adjacent cell so that the organism within becomes surrounded by both the cell membrane of the protrusion and the cell membrane of the second cell. When this double-membraned endosome is lysed, the organisms are released into the cytoplasm of the latter. Further evidence that such protrusions are involved in cell-to-cell invasion is the requirement for host cell E-cadherin, a calcium-dependent cell adhesion molecule localized to the intermediate junctions.<sup>48</sup> In cells that lack the ability to produce E-cadherin, abortive protrusions develop in which the bacteria fail to intimately interact with the inner face of the host membrane and lose contact with actin inside the protrusions. The final stage of intercellular invasion, lysis of the double cell membrane itself, is mediated via IpaB, IpaC, and IpgC.<sup>49</sup> In vivo, secondary epithelial cell invasion by *Shigella* is followed by cell-to-cell invasion and bacterial multiplication. This results in necrosis and sloughing of infected epithelial cells, creating focal microulcerations of the mucosa, primarily in the terminal ileum and colon, with the intensity of infection greatest in

**FIGURE 19-4** Intracellular movement of *Shigella flexneri* within HeLa cells, stained with fluorescein-labeled phalloidin, which specifically binds to polymerized actin. The actin tails are labeled and may be seen as bright streaks within the cytoplasm as the organism is pushed forward by the “actin motor” created by actin polymerization. Organisms that have moved out to the plasma membrane and are protruding from the plane of the membrane, the so-called fireworks, are indicated by the arrow.

the rectum and distal colon. The basis for this preferential localization in the colon is not presently understood.

These inflammatory processes persist longer in children than in adults, perhaps reflecting the immunologic immaturity in young children. Clearance of disease symptoms likely involves a combination of normal intestinal cell turnover, killing of *Shigella* by the innate defenses (e.g., PMNs), down-modulation of inflammation, and the development of specific immunity for final pathogen clearance. Epidemiologic evidence indicates that immunity to *Shigella* is serotype-specific, based on LPS; however, the precise nature of protective immunity, for example, mucosal immunoglobulin A (IgA) versus serum IgG, is not known.

*S. dysenteriae* type 1, but no other species of *Shigella*, makes a cytolethal protein toxin called Shiga toxin. This toxin binds to glycolipid receptors on the surface of cells, which leads to its uptake via a process of receptor-mediated endocytosis.<sup>50</sup> The active enzymatic portion of the toxin is transported to the Golgi region and then in retrograde fashion to the endoplasmic reticulum, where it catalytically and irreversibly inhibits host ribosomal protein synthesis. Although the role of Shiga toxin in human disease has not been fully clarified, experiments in monkeys comparing infection with isogenic wild-type virulent *S. dysenteriae* type 1 and a Shiga toxin<sup>-</sup> mutant differing only in toxin production demonstrate that toxin<sup>-</sup> *S. dysenteriae* 1 causes uncomplicated shigellosis and toxin-producing strains cause more severe gut inflammation, ulceration, and capillary damage.<sup>51</sup> Shiga toxin-producing *Shigella*, but not nontoxigenic species, are epidemiologically linked to the development of HUS. This association is strengthened by the finding that serotypes of *E. coli* that produce the structurally and biochemically similar Shiga toxins 1 and 2 are also strongly associated with HUS.<sup>52</sup>

## DIAGNOSIS

Specific diagnosis of *Shigella* infection depends primarily on isolation of the organism from microbiologic cultures of a stool or rectal swab sample, preferably the former because of the better yield. Samples that cannot be cultured rapidly (best at the bedside) should be inoculated onto transport media such as buffered glycerol-saline, the preferred transport medium for isolation of *Shigella*, or Cary-Blair medium. It is best to use both a moderately selective medium for gram-negative organisms, such as MacConkey<sup>46</sup> or deoxycholate citrate agar (DCA), and a more highly selective medium such as xylose-lysine-deoxycholate (XLD),<sup>47</sup> Hektoen enteric (HE), or *Salmonella-Shigella* (SS) agar.<sup>48</sup> *Shigella*, as well as *Salmonella*, fails to change the color of the pH indicator in the agar because of its inability to ferment lactose, allowing the technician to pick putatively pathogenic lactose-negative colonies for further identification, for example, subculture to triple sugar iron (TSI) agar or Kligler iron agar (KIA). On these media, *Shigella* are nonmotile, produce an alkaline slant and acid butt owing to their inability to ferment lactose aerobically in the slope and the anaerobic fermentation of glucose in the butt, and do not produce hydrogen sulfide or gas. Isolates that fulfill these criteria can be confirmed and speciated by serologic methods, using specific grouping antisera.

In many areas of the tropics, microbiological tests are not readily available, and the diagnosis must be based on clinical

and simple laboratory features. Many practitioners in endemic areas still believe that dysentery is more commonly amebic in etiology, but there is ample evidence that patients with the dysentery syndrome, including both children and adults, are far more likely to be infected with *Shigella*.<sup>53</sup> The clinical and laboratory features and stool examination in amebic and bacillary dysentery differ. A very short prehospitalization illness, high fever, and abundant fecal leukocytes (> 50 neutrophils per high-power field) are highly suggestive of shigellosis.<sup>54</sup> In the absence of microscopy or culture capability to make the specific diagnosis, patients with frank dysentery should be presumed to have shigellosis and treated empirically for this infection. In the field setting, the diagnosis of clinical dysentery can be established by community health workers who either observe the characteristic dysenteric stool or obtain a history of bloody stools from the mothers, who have been shown to be reliable historians of stool character.<sup>55</sup>

Modern rapid methods for diagnosis of *Shigella* infection have been developed. These include fluorescent antibody staining for *S. dysenteriae* type 1, which appears to have high sensitivity (92%) and specificity (93%),<sup>56</sup> immunomagnetic isolation followed by polymerase chain reaction<sup>57</sup> or monoclonal antibodies<sup>58</sup> for identification, and isotope- or enzyme-labeled DNA probes for virulence markers specific for *Shigella*, some of which are also present in the much rarer *Shigella*-like enteroinvasive *E. coli*.<sup>59,60</sup> To date, with one exception, no reliable rapid method is commercially available or in routine use anywhere. The exception is an enzyme immunoassay for Shiga toxin that can be done directly on stool and is indicative of the presence of a Shiga toxin-producing *S. dysenteriae* type 1 or *E. coli* serotype, such as O157. This test is in use in some developed countries for rapid diagnosis of *E. coli* O157 and other Shiga toxin-producing *E. coli* infections.<sup>61</sup> Serologic antibody testing is useful for epidemiologic studies but not for diagnosis of acute disease, especially in endemic areas where the majority of the population is seropositive from prior exposure.<sup>62</sup>

## TREATMENT AND PROGNOSIS

Antimicrobial therapy is the cornerstone of treatment for shigellosis. In the absence of effective antimicrobial therapy, mortality due to *Shigella* infection is appreciable, especially from infection with *S. dysenteriae* type 1, which has been associated with a mortality rate in excess of 10%, particularly in the young and the elderly.<sup>63</sup> Although *S. sonnei* is generally a mild, self-limited infection in developed countries, infection with any *Shigella* species can be lethal in the malnourished or immunocompromised patient in developing countries. However, antimicrobial therapy given within 72 hours of symptoms not only brings prompt resolution of the dysenteric symptoms but also prevents the more serious complications of the infection.<sup>64</sup> All persons who have dysentery and presumed *Shigella* infection should therefore be treated with an appropriate antimicrobial agent when first seen; the results of culture and susceptibility testing, if available, can then be used to modify the initial therapy if necessary.

To be useful in the treatment of shigellosis in the tropics, an antimicrobial agent should be active in vitro against the infecting strain of *Shigella*; should be safe for use in children

under 5 years of age, who are the target for the majority of *Shigella* infections; preferably can be administered orally; should be demonstrated to be efficacious in controlled trials; and is inexpensive.<sup>65</sup> Because of the increasing prevalence of multiple drug-resistant strains, selection of an appropriate agent has become increasingly difficult. The older oral agents chloramphenicol and tetracycline are no longer effective because of the high prevalence of resistance. For the same reason, trimethoprim-sulfamethoxazole and ampicillin, until recently the drugs of choice for the treatment of shigellosis, are no longer useful in most developing countries.<sup>66</sup> Some drugs that are effective in vitro, such as oral extended-spectrum cephalosporins (e.g., cefixime), are ineffective in vivo,<sup>67</sup> as are nonabsorbable agents, such as furazolidone, despite advertising claims to the contrary.

Thus, current options for treating *Shigella* infections in the tropics are limited (Table 19-1). Oral agents shown to be effective in clinical trials against multiply resistant strains are nalidixic acid (to which most strains of *S. dysenteriae* type 1 but not *S. flexneri* are now resistant), the fluoroquinolones such as ciprofloxacin and others, the  $\beta$ -lactam agent pivamdinocillin,<sup>68</sup> and azithromycin.<sup>69</sup> The parenteral agent ceftriaxone has also shown efficacy, even when given for just 2 days.<sup>70</sup> The major concern with the recommendation of ceftriaxone for severe disease due to resistant strains is that the drug may not be available in the community, will be more expensive than established oral drugs, and requires parenteral administration. The overall guiding principles in the choice of an agent for shigellosis in developing countries include availability, cost, and the pattern of resistance in the community.

Short-course (3-day) ciprofloxacin, shown to be effective, can therefore reduce the costs of treatment.<sup>71</sup> The danger is the selection of resistance if the drug is overly and indiscriminately used.<sup>72</sup> If shigellosis is suspected on the basis of clinical findings, empiric antimicrobial treatment is recommended. If the patient does not improve within 48 hours, then infection with a *Shigella* strain resistant to the drug being used or infection with another organism should be suspected, and therapy changed to an appropriate alternative agent. It is essential to know the resistance pattern in each geographic area to devise an empirical strategy of first- and second-line drugs, and this requires a surveillance system with an adequate testing laboratory, neither of which may be available in developing countries.

Because patients with shigellosis are rarely severely dehydrated, intravenous rehydration is not necessary. Oral rehydration therapy is generally sufficient to reverse the mild-to-moderate dehydration that may occur. Severe hyponatremia can be treated IV with either normal saline, or if close monitoring is available, a 3% NaCl solution. Administration of 12 mL/kg body weight of the latter will raise the serum sodium concentration by 10 mmol/L. The danger is that rapid correction of hyponatremia can be accompanied by central nervous system complications.

Patients with shigellosis should be fed to the extent they are willing to eat (breast milk or solid foods, depending on age) to prevent acute hypoglycemia as well to militate against the development or aggravation of malnutrition. Feeding may be limited because of diminished appetite, at least until the infection is controlled with antimicrobial therapy.<sup>73</sup>

**Table 19-1** Antimicrobial Agents for Treatment of Shigellosis in Tropical Countries

Agent	Adult Dose	Pediatric Dose*	Frequency†	Duration	Comment
Nalidixic acid	500 mg	15 mg/kg	4 times daily	5 days	Most strains of <i>Shigella dysenteriae</i> type 1 now resistant.
Pivamdinocillin	400 mg	25 mg/kg	4 times daily	5 days	Not widely available, generic name is pivmecillinam outside the United States.
Fluoroquinolones	‡	10 mg/kg	Twice daily	3 days	Not approved for use in children in some countries; risk of toxicity in children is small when used in standard dose and duration.
Azithromycin	500 mg on day 1; 250 mg thereafter	10 mg/kg on day 1; 5 mg/kg thereafter	Once daily	5 days	Clinical trials have not been conducted in children.
Trimethoprim-sulfamethoxazole	160 mg trimethoprim–800 mg sulfamethoxazole	4 mg/kg trimethoprim – 20 mg/kg sulfamethoxazole	Twice daily	5 days	Most <i>Shigella flexneri</i> and <i>S. dysenteriae</i> type 1 strains are resistant.
Ampicillin	500 mg	25 mg/kg	4 times daily	5 days	Most <i>S. flexneri</i> and <i>S. dysenteriae</i> type 1 strains in tropical countries are resistant.

\*Maximum pediatric dose is adult dose.

†Single-dose therapy with ciprofloxacin 1 g, or norfloxacin 800 mg, is effective for non-*S. dysenteriae* type 1 infections.

‡Ciprofloxacin (500 mg), norfloxacin (400 mg), and enoxacin (200 mg) have all been found to be effective in clinical trials.

Restoration of nutritional status is most rapidly achieved if a high-calorie, preferably high-quality protein-rich diet can be provided during convalescence. But, because it takes considerably longer to replenish nutrient stores than it does to create the deficit during infection, the parents of a child recovering from shigellosis must be encouraged to feed their child more than normal during the prolonged convalescent period, until satisfactory weight gain has occurred.

Treatment of complications of disease is largely supportive. Patients with seizures do not need anticonvulsant therapy, since more than one seizure is uncommon.<sup>46</sup> Where readily available, anticonvulsants are often given before the cause of the seizure becomes apparent. Patients with HUS may require both transfusions and peritoneal dialysis. Even with these interventions, mortality from *S. dysenteriae*-associated HUS remains higher than in HUS associated with other infections.<sup>74,75</sup> Whether this is because the underlying infection is more severe or because facilities for managing these complications in areas where *S. dysenteriae* type 1 outbreaks occur are often poor, or both, is uncertain. Toxic megacolon can be associated with a mortality rate as high as 50%.<sup>47</sup> Colectomy, which may be necessary in treating megacolon due to ulcerative colitis in developed countries, is rarely an option in developing countries because long-term care for a child with a colectomy usually is unavailable. If perforation occurs in this setting, simple surgical repair and primary closure in two layers plus aggressive fluid therapy are recommended. Rectal prolapse will resolve on its own as the infection wanes; in the interim, the prolapsed tissues should be kept moist and protected against injury. Suspected bacteremia or sepsis should be treated with parenteral, broad-spectrum antibiotics.

## PREVENTION AND CONTROL

Because of the importance of person-to-person transmission and the low inoculum requirement, the primary method of preventing *Shigella* infections is good personal hygiene. Caretakers of children should wash their hands after defecating and after caring for infants who have defecated, and always before preparing food.<sup>70</sup> Hand washing with soap is preferred, but if soap is not available in a village setting then traditional practice of washing with an abrasive substance (e.g., sand or ash) or even with water alone is better than not washing. In addition to the difficulties encountered in changing established behaviors such as inadequate hand washing, a further limitation of this approach in developing countries is that water is often not available. Although flies are not a major means of dissemination of *Shigella*, in settings with poor hygiene practices and an inadequate environmental sanitation infrastructure, fly control reduces the prevalence of infection.<sup>76</sup>

The other approach to prevent *Shigella* infection is immunization. However, it has proved difficult to develop safe and effective vaccines for shigellosis, in part because the key protective antigens and the mechanism of protective immunity remain unclear. Pioneering early vaccine studies demonstrated that protective immunity against shigellosis is serotype-specific. For example, when two groups of children of over 10,000 each were immunized with different streptomycin-dependent multivalent live oral vaccines, protection was documented against the serotypes and species included in the vaccine they received.<sup>77</sup> Clinical data in experimental

human shigellosis models support this concept, as previous infection protects against reinfection with the same *Shigella* species and serotype.<sup>78,79</sup> However, the specific and relative roles of humoral versus cell-mediated responses and mucosal versus systemic immunity in recovery from infection remain uncertain, hampering the development of effective vaccines. Because traditional parenteral killed vaccines have been ineffective,<sup>80</sup> attention has shifted to alternative approaches, including the use of oral immunization with live attenuated *Salmonella typhi* expressing *Shigella* LPS genes<sup>78</sup> or with live attenuated *Shigella* strains,<sup>81</sup> immunization with cloned virulence factors,<sup>82</sup> and the use of parenteral LPS-protein conjugates.<sup>83</sup> To date, no acceptable safe and sufficiently effective vaccine has been developed, although multiple approaches have been tried. On the basis of its role in severe disease in the rhesus monkey model,<sup>39</sup> a simple approach to protect against HUS due to *S. dysenteriae* type 1 or Shiga toxin-producing *E. coli* infections would be to immunize against the toxins involved, using simple toxoids or more complex, genetically inactivated toxin molecules or subunits.<sup>84</sup> Such a vaccine should also decrease the incidence of HUS due to *S. dysenteriae* type 1, as well as Shiga toxin-producing *E. coli*, but this remains to be demonstrated.

# Campylobacter Infections

BAN MISHU ALLOS  
MARTIN J. BLASER

## INTRODUCTION

Campylobacters are bacteria that often produce an acute gastrointestinal illness. Infections with these organisms occur in every part of the world, including arctic, temperate, and tropical climates.<sup>1</sup> In developing countries, especially those in tropical areas, they are hyperendemic and important causes of morbidity and possibly mortality in young children. *Campylobacter* infections also are an important cause of diarrhea in persons residing in developed countries who travel to developing countries in the tropics.<sup>2,3</sup>

## AGENT

*Campylobacter* species are microaerophilic, comma-shaped, gram-negative rods that were first recognized as causes of infectious abortion in animals in the early twentieth century<sup>4</sup> and later were determined also to cause infectious abortion in women.<sup>5</sup> Over the next decades, the organisms were reported to cause bacteremia, meningitis, endocarditis, and abscesses in immunocompromised patients.<sup>6,7</sup> A group of related organisms also were isolated from the blood of patients with diarrhea.<sup>8</sup> During the last three decades of the twentieth century, campylobacters were recognized as one of the most common bacterial causes of diarrhea worldwide.

Although the organisms were first called *Vibrio*, they were assigned to a new genus, *Campylobacter*, in 1973<sup>9</sup>; this scheme was later modified so that the opportunistic organism was called *Campylobacter fetus*, and the related vibrios were called *Campylobacter jejuni* and *Campylobacter coli*.<sup>10</sup> In 2000, the complete genome of *Campylobacter jejuni* was sequenced.<sup>11</sup>

The use of filtration with antibiotic-free culture systems<sup>12</sup> and other newer techniques<sup>13,14</sup> have led to the recognition that many other “atypical” species of *Campylobacter* and closely related genera also may produce human disease<sup>15</sup> (Table 20-1). Such species include *C. fetus*, *Campylobacter upsaliensis*, *Campylobacter hyointestinalis*, *Campylobacter lari*, *Helicobacter cinaedi*, *Helicobacter jennelliae*, *Arcobacter cryaerophila*, *Arcobacter butzleri*, *Campylobacter jejuni* subspecies *doylei*, *Campylobacter concisus*, *Campylobacter mucosalis*, *Campylobacter rectus*, and *Campylobacter sputorum*. New pathogenic species of *Campylobacter* are being identified with some regularity.

In tropical countries such as South Africa, such “atypical” campylobacters comprise more than 50% of the *Campylobacter*

species isolated.<sup>16–18</sup> In contrast, in the United States and other developed nations, *C. jejuni* accounts for greater than 95% of *Campylobacter* species isolated.<sup>19</sup> Other studies of *Campylobacter*, in Thailand,<sup>20</sup> Hong Kong,<sup>21</sup> and the Central African Republic,<sup>22</sup> show a higher incidence of *C. coli* relative to that seen in industrialized nations. However, since methods designed to optimize detection of *C. jejuni* might not support growth of other species, the contribution of these organisms to the burden of human disease may be underestimated.

Campylobacters grow best at the body temperatures of warm-blooded animals. Optimal growth for *C. jejuni* is at 42°C at which campylobacters will survive only a few days, but at 4°C they can persist for weeks in substances such as water, feces, urine, or milk.<sup>23</sup> Similarly, the organism may flourish and grow in an alkaline environment but will not last 5 minutes at pH less than 2.3.<sup>23</sup>

## EPIDEMIOLOGY

The epidemiology of *Campylobacter* infections is markedly different in tropical developing countries than in the developed world (Table 20-2). Infections are hyperendemic among young children. In tropical countries such as Bangladesh, South Africa, The Gambia, Zaire, India, Australia, Indonesia, and China, the rate of isolation of *Campylobacter* is greatest in infants and declines with age.<sup>24</sup> Although national surveillance programs for campylobacteriosis do not exist in developing countries, estimates from laboratory-based surveillance suggest that the incidence of this infection among children less than 5 years of age may be more than 100 times higher than the rate among children in developed nations.<sup>25</sup> Campylobacters frequently can be isolated from asymptomatic children and adults in developing countries.<sup>26</sup> In contrast, in developed countries, infection is almost always recognized in association with illness, recognized asymptomatic infections are uncommon, and young children are not at greatest risk.

In the developing nations mentioned previously, breast-fed children are usually protected, but a high rate of infection with concomitant watery diarrhea is observed after they are weaned.<sup>27</sup> In addition to early weaning, close proximity to animals and lack of toilets are important risk factors for the development of early-childhood diarrheal illnesses in general, and those caused by *Campylobacter* in particular.<sup>25,28</sup> The apparent absence of multiple infections within a household<sup>29</sup> suggests that person-to-person transmission is not an important mode of spread, even in developing countries. Infections in adults and older children usually are asymptomatic and durations of excretion are short, suggesting that acquired immunity is protective. The importance of acquired protective immunity is further supported by studies in developing countries showing that rising serum antibodies to *Campylobacter* are associated with a lower rate of infection.<sup>30,31</sup>

Outbreaks of *Campylobacter* infection, which occur regularly in developed countries, do not occur in developing countries because of this high level of immunity. Campylobacters are ubiquitous in the environment in tropical climates and infections occur year-round. The late summer and early fall peak in the incidence of *Campylobacter* infections observed in temperate climates is not seen in tropical countries.<sup>24,26,32</sup>

**Table 20-1** Clinical and Epidemiologic Features Associated with “Atypical” *Campylobacters* and Related Organisms

Species	Clinical Presentation	Epidemiologic Data
<i>C. coli</i>	Fever, diarrhea, abdominal pain	Clinically and epidemiologically similar to <i>C. jejuni</i>
<i>C. fetus</i>	Bacteremia, sepsis, meningitis, vascular infection, abortion	Found in healthy sheep and cattle; may cause spontaneous abortion and infertility
<i>C. upsaliensis</i>	Watery diarrhea, low-grade fever, abdominal pain	Found in dogs, cats; may have autumn seasonality in tropical countries
<i>C. lari</i>	Abdominal pain, diarrhea	Seagulls colonized; transmitted to human via contaminated water
<i>C. hyointestinalis</i>	Watery or bloody diarrhea, vomiting, abdominal pain	Causes proliferative enteritis in swine
<i>H. fennelliae</i> , <i>H. cinaedi</i>	Chronic mild diarrhea, proctitis, abdominal cramps	Increased in homosexual men and in children in developing countries; may cause bacteremia in HIV+ hosts
<i>C. jejuni</i> subspecies <i>doylei</i>	Diarrhea	Role as a human pathogen not established
<i>A. cryaerophila</i>	Diarrhea, rarely bacteremia	Isolated from mussels in brackish water
<i>A. butzleri</i>	Fever, diarrhea, abdominal pain, nausea; rarely bacteremia	Enzootic in nonhuman primates
<i>C. sputorum</i>	Pulmonary, axillary, groin, and perianal abscesses	Has been isolated from dairy cows
H <sub>2</sub> -requiring campylobacters*	Periodontitis; less commonly, diarrhea	Role as a human pathogen not established
<i>H. pullorum</i>	Uncommon human pathogen; occasionally associated with diarrhea, rarely bacteremia	Isolated from asymptomatic hens and from hens with hepatitis
<i>H. rappini</i>	Gastroenteritis; few case reports document bacteremia	Animal reservoir not known

\*Includes *C. rectus*, *C. curvus*, and *C. concisus*.

Although rotavirus, enterotoxigenic *Escherichia coli*, and *Shigella* infections are more common than *Campylobacter* as causes of diarrhea in tropical countries,<sup>28,33,34</sup> campylobacters are the most common bacterial cause of community-acquired diarrhea in developed countries.<sup>35,36</sup> However, even in developing countries, *Campylobacter* infections are increasing and in some areas

surpassing *Shigella* and *E. coli* as causes of diarrhea.<sup>37</sup> Furthermore, the prevalence of *Campylobacter* infections is higher in tropical climates than in cooler ones. Even among healthy, asymptomatic children in countries such as Bangladesh, South Africa, The Gambia, and Central African Republic, *Campylobacter* may be isolated from 10% to 40% of children

**Table 20-2** Clinical and Epidemiologic Characteristics of *Campylobacter* Infections in Developed versus Tropical Developing Countries

Characteristic	Developed Countries	Developing Countries
Peak age group affected	15–29 yr	<2 yr
Endemicity of infection	Endemic	Hyperendemic
Occurrence of outbreaks	Common	Rare
Seasonality	Summer and fall peaks	Year-round
Predominant mode of transmission	Food-borne	Uncertain
Clinical expression	Inflammatory	Noninflammatory
Asymptomatic infection	Uncommon	Usual
Nature of diarrhea	Inflammatory*	Watery
Abdominal cramps	Common	Rare
Bacterial load in stools of infected persons	High	Low
Presence of immunity in typical adult	No	Yes

\*Stools frequently contain gross or occult blood, and leukocytes.

from a single culture.<sup>26,29,38–40</sup> *Campylobacter* infection is one of the most common causes of diarrhea among travelers to developing countries<sup>41</sup> and in Thailand is the most common cause.<sup>31,42</sup>

Most human infections with *Campylobacter* in developing countries occur because of consumption of or exposure to animals or their products. *Campylobacters* live as commensals in the gastrointestinal tract of a variety of animals, especially avian species. Not surprisingly, *campylobacters* are frequently isolated from poultry and other animals in developing countries,<sup>43–48</sup> but the extent of the contribution of this source to human illness has not been determined.<sup>49</sup> In Africa, *campylobacters* also have been isolated from surface domestic water sources used for human consumption<sup>50</sup> and from dairy products.<sup>51</sup> The main vehicles of human infection in developed countries are water, milk, raw meat, and most importantly, poultry. Person-to-person transmission of *Campylobacter* is infrequent in both developed and developing countries.

## DISEASE

In developing countries, the clinical consequences of infection with *Campylobacter* differ from those seen in the developed world. When children in tropical settings develop diarrhea as a result of *Campylobacter* infection, it frequently is watery and there usually is little or no evidence of an inflammatory process.<sup>52</sup> Although symptomatic infection is most likely to occur during the first few months and years of life, asymptomatic infections outnumber symptomatic ones by 2 to 1, even among children less than 5 years of age.<sup>53</sup> Infection among children in tropical countries is quite common; more than two infections per year are likely during the first 5 years of life.<sup>29,53</sup> Among young children in Bangladesh, the estimated rate is eight *Campylobacter* infections per year.<sup>26</sup>

In developed areas, *Campylobacter* infections usually produce an acute gastrointestinal illness that is indistinguishable from illness caused by other “inflammatory” enteric bacteria such as *Salmonella* and *Shigella*. Illness usually begins abruptly with abdominal cramps and diarrhea. Children in developing countries who develop symptomatic *Campylobacter* infection also typically experience loose stools with mucus, along with fever and vomiting.<sup>54</sup> However, although half of *Campylobacter*-infected patients presenting for medical attention in developed countries have bloody diarrhea,<sup>35</sup> in tropical climates the diarrhea usually does not contain blood. Less than one third of *Campylobacter*-infected children in Thailand have bloody stools; most have mucoid stools that are neither watery nor bloody; about one third have watery diarrhea.<sup>20,54</sup> *Campylobacter* infection among persons living in tropical areas also are less likely to produce abdominal cramps.<sup>26</sup> The illness usually resolves within 1 to 2 weeks; about 20% of patients will have relapsing symptoms lasting several weeks. Although *Campylobacter* infections occur frequently in HIV-infected persons residing in developed countries,<sup>55</sup> a similar phenomenon is not always observed in developing nations.<sup>56–58</sup>

Complications of *Campylobacter* infections are rare and usually the result of local invasion. Massive gastrointestinal hemorrhage may occur. Other complications include cholecystitis, pancreatitis, obstructive hepatitis, and splenic rupture.<sup>59–62</sup> Neonatal sepsis and death can occur if the mother is

infected during the third trimester.<sup>63</sup> Extraintestinal complications of *Campylobacter* infections are rare<sup>64</sup> but are more common in malnourished children. Such complications include bacteremia, meningitis, and purulent arthritis. Infection may lead to fulminant sepsis and death. The postinfection complication, Guillain-Barré syndrome (GBS), occurs at an estimated rate of 1 per 2000 infections.<sup>65</sup> A particularly severe form of GBS, acute motor axonal neuropathy, occurs in seasonal epidemics among children in rural China and also may be associated with preceding *C. jejuni* infection.<sup>66</sup> Reactive arthritis also may occur after *Campylobacter* infection and is most common in persons who carry the HLA-B27 phenotype.<sup>67–69</sup> *C. jejuni* was recently implicated as a cause of immunoproliferative small intestine disease (a form of lymphoma) in a 45-year-old woman in Cameroon.<sup>70</sup>

In patients in developed countries, the pathologic lesion of *Campylobacter* enteritis is infiltration of the lamina propria with acute and chronic inflammatory cells and destruction of epithelial glands with crypt abscess formation.<sup>71</sup> The site of tissue injury is usually the jejunum, ileum, and colon.<sup>71,72</sup> This nonspecific colitis may be indistinguishable from ulcerative colitis or Crohn's disease; hence the importance of diagnosing this treatable infection before immunosuppressive therapy is given for inflammatory bowel disease. The pathology of *Campylobacter* enteritis among patients in tropical and developing countries has not been well described but, based on the clinical presentation, is presumably milder.

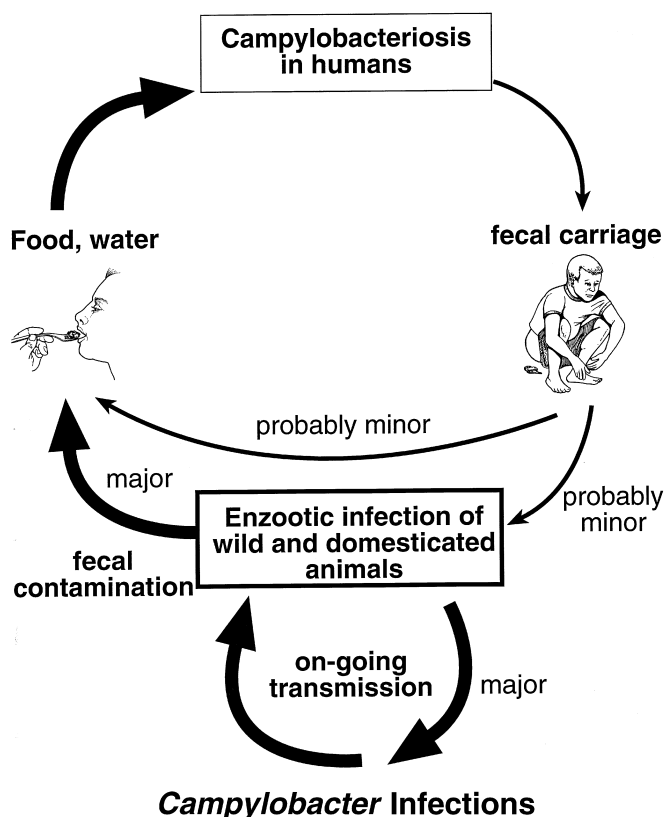

## PATHOGENESIS AND IMMUNITY

Three factors important in the ability of *Campylobacter* to produce illness include the dose of organisms reaching the small intestine, the host's immunity to the organism, and the virulence of the particular strain. Infection leads to multiplication of the organism in the intestine. The number of bacterial cells required to cause illness is unknown, but a high dose is likely needed to infect 50% of subjects.<sup>73</sup> In general, the higher the inoculum, the shorter the incubation period (usually 1 day to 1 week) and the higher the attack rate.

In developed countries, *Campylobacter*-infected persons shed between 10<sup>6</sup> and 10<sup>9</sup> colony-forming units (CFU) per gram of stool.<sup>23</sup> However, the intestinal bacterial load is lower among similarly infected persons in developing nations.<sup>30</sup> Furthermore, in developing areas, the duration and number of organisms excreted are highest in infants and decline with age, also consistent with increasing acquisition of immunity.<sup>54</sup>

Characteristics of *campylobacters* that enable them to adhere to and invade intestinal cells include the presence of flagella, high-molecular-weight plasmids, superficial adhesins, fimbriae, and chemotactic factors.<sup>73–80,81</sup> *Campylobacters* must be flagellated to colonize, invade, and cause disease.<sup>82</sup> Although the bacteria do not possess fimbriae per se, fimbriae-like filaments enable the organisms to attach to epithelial cells.<sup>83</sup> Additionally, several *C. jejuni* surface proteins (e.g., PEB1, CadF) appear to function in attachment and subsequent colonization and invasion.<sup>83</sup> Invasion of epithelial cells by *C. jejuni* results in cellular injury and, ultimately, in diarrhea. The mechanism of invasion is complex and not completely understood.<sup>84</sup>

Despite early reports to the contrary,<sup>85</sup> the low level of enterotoxin production that occasionally has been observed

in vitro does not appear to be important in the pathogenesis of *Campylobacter* infections.<sup>81,86</sup> Enterotoxin production cannot be demonstrated in vivo, and infected patients do not form antibodies against enterotoxin.<sup>87</sup> All *C. jejuni* isolates possess a gene that codes for cytolethal distending toxin; however, not all isolates produce this toxin, and its role in causing disease is not established.<sup>88</sup>

Specific immunity to *Campylobacter* may be acquired. In developing countries where these infections are hyperendemic, infection and illness rates decline with age, again suggesting the acquisition of immunity. Volunteer studies also have shown that short-term specific immunity to *Campylobacter* occurs.<sup>73,89</sup> Humoral immunity appears to play an important role in containing *Campylobacter* infection. After infection, serum antibodies (IgA, IgG, and IgM) peak in 2 to 4 weeks, then rapidly decline.<sup>90</sup> The importance of humoral immunity is further supported by studies showing that in hypogammaglobulinemic patients, *Campylobacter* infections are severe, prolonged, and difficult to eradicate.<sup>91</sup> Children in tropical settings develop steadily rising serum IgA antibodies to *Campylobacter*. Once these high levels are achieved, IgG levels, which also rise through early childhood, begin to decline.<sup>54,92,93</sup> These data suggest that frequent exposure to *Campylobacter* leads to the development of solid "gut immunity," which precludes sensitization of IgG-producing cells. Such gut immunity correlates well with the declining incidence of infection with age, the lower proportion of infections that are symptomatic, and the reduced bacterial level and duration of excretion.<sup>54</sup>

Persons with human immunodeficiency virus (HIV) infection have more frequent, persistent, severe, and extraintestinal *Campylobacter* infections than the general population in

developed nations.<sup>94,95</sup> Although these observations could suggest that cellular immunity also plays an important role in protection against *Campylobacter*, many such patients have defects in humoral responses as well.

Serum killing of *Campylobacter* species occurs via complement-mediated bactericidal activity.<sup>96</sup> This could explain why bacteremia due to *Campylobacter* species is uncommon except in immunodeficient persons, or is due to the serum-resistant *C. fetus*.<sup>96</sup> Serum-resistant campylobacters have been isolated from the cerebrospinal fluid of patients with meningitis.<sup>97</sup>

## DIAGNOSIS

In developing countries, the simplest and most inexpensive method for diagnosis of *Campylobacter* infection is direct examination of stools after Gram or Wright staining. Stools also can be directly examined for the presence of white blood cells or lactoferrin and erythrocytes, which are nonspecific findings associated with inflammatory agents but that also suggest the presence of a bacterial enteric pathogen, such as *Campylobacter*.

The gold standard for detection of *Campylobacter* infection is culture of the organism from stool, blood, or other site of infection. Because *Campylobacter* infection cannot be differentiated from infections due to other bacterial enteric pathogens on clinical grounds, isolation of the organism using a selective technique is the only way to make the diagnosis with certainty. Cephalothin-containing selective media will suppress most fecal flora while permitting the growth of most *C. jejuni* strains. However, some *Campylobacter* species (and even a few *C. jejuni* strains) are cephalothin-susceptible, and must be isolated on less selective media or on antibiotic-free media after filtration of the stool sample. In tropical countries, many patients may have mixed infections with *Campylobacter* and other enteric pathogens.<sup>20,54</sup> Therefore, the precise contribution of *Campylobacter* infection to these children's illnesses may be difficult to assess.

*Campylobacter* infection also may be mistaken for inflammatory bowel disease. *Campylobacter* enterocolitis may produce crypt abscesses (which are frequent in ulcerative colitis) and granulomas (which are common in Crohn's disease).<sup>71,72,98</sup> Persons suspected of having inflammatory bowel disease should have cultures for several different *Campylobacter* species performed as part of their diagnostic workup.

Serologic testing occasionally may be useful for detecting recent *Campylobacter* infection.<sup>96,99</sup> However, this technique is unlikely to be helpful in tropical developing countries where infection is hyperendemic and background infection rates are high. Polymerase chain reaction (PCR) to detect *Campylobacter* in stools is beginning to be used in some clinical laboratories in developed nations.<sup>100,101</sup> However, the clinical significance of a positive PCR assay in a patient in a developing country might be difficult to interpret and the costs associated with such testing preclude wide usage.

## TREATMENT AND PROGNOSIS

Antimicrobial treatment of *Campylobacter* infections, if initiated early in the illness, reduces the duration of bacterial excretion in stools.<sup>102,103</sup> However, most patients with *Campylobacter* enteritis, and certainly those with asymptomatic or mild infection, do

not need antimicrobial therapy. Even patients whose symptoms lead them to seek medical care may not require measures other than encouragement to keep well hydrated. Occasionally, intravenous fluids are needed, especially in the very young and very old. In developing countries, oral hydration solutions are the best method of maintaining fluid and electrolyte balance, unless volume depletion is severe. The prognosis for most patients with *Campylobacter* infection is favorable; symptoms usually resolve within 1 week without antimicrobial therapy.

Antibiotics should be given to *Campylobacter*-infected patients in certain high-risk groups or clinical circumstances. Because *Campylobacter* infection may have deleterious effects on the fetus, pregnant women should receive prompt therapy.<sup>63</sup> Similarly, HIV-infected or other immunocompromised patients should receive antibiotics. With the expanding HIV epidemic in developing countries, extraintestinal infection will be increasingly common. Immunocompetent persons with fever greater than 38.3°C (101°F), bloody stools, symptoms lasting more than 1 week, or worsening symptoms also may benefit from antimicrobial therapy.

Campylobacters are susceptible to a wide variety of antimicrobial agents, including macrolides, quinolones, nitrofurans, and aminoglycosides. Care should be taken before prescribing tetracycline because more than 20% of campylobacters are resistant.<sup>104,105</sup> Susceptibility to ampicillin, metronidazole, and trimethoprim-sulfamethoxazole is variable. There is almost universal resistance of *Campylobacter* to cephalosporins, penicillin, vancomycin, and rifampin.

Erythromycin remains the treatment of choice for most patients with infections due to *Campylobacter*. Erythromycin has low toxicity, has a relatively narrow spectrum of activity, and is inexpensive. Because erythromycin stearate is incompletely absorbed, it can exert a local effect throughout the bowel, in addition to its systemic effects. In most developed countries, the rate of erythromycin resistance among *Campylobacter* species has remained under 10%.<sup>106–108</sup> Higher rates of resistance have been reported from developing countries, such as Thailand,<sup>33</sup> but resistance remains low in other countries, such as India and Kenya.<sup>109–110</sup> The rate of erythromycin resistance is substantially higher among *C. coli* strains.<sup>105,111–113</sup> The newer macrolides, azithromycin and clarithromycin, have excellent activity against *Campylobacter*.<sup>114–117</sup> Although they achieve higher concentrations in tissue, they provide little clinical advantage over erythromycin and are considerably more expensive. Strains resistant to erythromycin also will be resistant to these newer macrolides. The activity of clindamycin against *C. jejuni* is equivalent to that of erythromycin.

At one time, it appeared that quinolones, such as ciprofloxacin, had emerged as the treatment of choice for bacterial diarrhea in general and for *Campylobacter* enteritis in particular.<sup>118</sup> Unfortunately, rapidly emerging resistance of campylobacters to quinolones in tropical regions and in other parts of the world has limited their effectiveness.<sup>103,119,120</sup> Widespread use of fluoroquinolones in poultry has led to the transfer of antibiotic-resistant strains to humans.<sup>121–122</sup> Nalidixic acid resistance commonly but not invariably crosses with resistance to ciprofloxacin.<sup>105</sup> Resistance to this agent has paralleled the increasing resistance to fluoroquinolones.

In special circumstances when therapy is required, and when a patient is intolerant of many agents or when a strain has an unusual antibiotic resistance pattern, alternative agents

such as chloramphenicol may be used; nearly all campylobacters are susceptible to chloramphenicol.<sup>105,123</sup> This agent is especially useful in tropical developing countries because of its low cost. For persons with bacteremia and other extraintestinal suppurative infections, gentamicin and imipenem are active against campylobacters and the rate of resistance to these agents is less than 1%. Gentamicin is ineffective against *Campylobacter* in the gut; therefore, oral therapy with an effective, absorbable drug also must be given.

## PREVENTION AND CONTROL

Campylobacters are so ubiquitous in the environment of most tropical developing nations that there is no possibility of reducing the reservoirs of infection. Rather, prevention must focus on interrupting the path of transmission to humans from animals, animal products, or environmental sources contaminated by animals or humans. Poultry, livestock, pets, and wild animals are the major reservoirs. Therefore, as for many bacterial enteric pathogens, a basic tenet of prevention is adequate hand washing; this is especially important in tropical areas for people who handle animals and food within a household. Especially important is the awareness of the necessity for proper cooking and storage of foods of animal origin.

The safe disposal of sewage and the protection and purification of water supplies also are fundamental to control of most diseases due to enteric pathogens, including *Campylobacter*. Programs to improve water safety in developing countries may impact the number of infections.<sup>124</sup> Excreta from sheep, cattle, and wild and domestic birds should not be allowed to contaminate a community's water supplies. Chlorination reliably inactivates *Campylobacter*.<sup>125</sup>

Control of *Campylobacter* infections in developing countries will likely be difficult unless an effective vaccine is developed. Because of the diversity of serotypes of *C. jejuni*, the possibility of vaccination for prevention of infection must be based on group antigens. Since *Campylobacter* infection of humans is "accidental" given that humans are not required for completion of their life cycle, the natural acquisition of immunity in developing countries and the identification of group antigens suggest that vaccination will be feasible. There is no proven benefit of antibiotic prophylaxis to prevent *Campylobacter* infection in travelers to tropical and subtropical environments.

SAMBA O. SOW

## INTRODUCTION

Cholera is a diarrheal illness caused by *Vibrio cholerae* O1 (and less often by serogroup O139), which in its severe form, cholera gravis, can rapidly and fatally dehydrate adults as well as children. Besides its clinical severity in the individual patient, cholera is one of the few bacterial diseases that is capable of true pandemic spread. Since 1961, when the seventh pandemic caused by *V. cholerae* O1 biotype El Tor began on the island of Sulawesi, El Tor cholera has progressively extended to involve all the inhabited continents. Since cholera is spread by contaminated water and food vehicles, its transmission is facilitated wherever populations are not served by treated water supplies and sanitation.

Several events in the last decade of the 20th century exemplify the epidemiologic and clinical importance of cholera and demonstrate why it commands special attention among practitioners of clinical and preventive tropical medicine. These events included

1. The return of cholera to Latin America in 1991, after a century of absence, and its rapid dissemination leading to more than 1 million cases by 1994<sup>1</sup>;
2. The explosive outbreak of El Tor cholera in Rwandan refugees in Goma, Zaire, resulting in approximately 70,000 cases and 12,000 deaths in July 1994<sup>2,3</sup>;
3. The appearance in 1992–1993 of epidemic cholera in the Indian subcontinent, caused for the first time by a *Vibrio cholerae* serogroup other than O1, so-called O139 Bengal.<sup>4,5</sup>

## AGENT

Medical historians debate whether cholera existed in ancient populations in the Indian subcontinent and the Middle East or only emerged in the early 19th century as a new infectious disease of humans. What is incontestable is that at least seven distinct pandemics of cholera have occurred since the first was recorded in 1817. The first six pandemics originated in the Ganges delta from which they spread progressively to involve other countries and continents. During the third and fourth pandemics, John Snow made hallmark descriptions of the epidemiology of cholera, suggesting that it was a contagion and incriminating its spread via sewage-contaminated municipal water.<sup>6</sup> Incredibly, these insights were made several

decades before Robert Koch isolated the causative bacterium in Egypt in 1883, during the fifth pandemic.<sup>7</sup>

In the 1950s, investigators in India demonstrated that cell-free supernatants of *V. cholerae* caused fluid accumulation in isolated loops of rabbit intestine, thereby implying the existence of an enterotoxin.<sup>8</sup> In the late 1960s, cholera enterotoxin was purified to homogeneity and shown to be composed of two different types of subunits noncovalently linked.<sup>9</sup> Also in the late 1960s, oral glucose/electrolyte solutions were shown to be effective in rehydrating patients with mild and moderate cholera, a clinical breakthrough that eventually revolutionized the therapy of diarrheal dehydration of all etiologies.<sup>10</sup>

*V. cholerae*, a motile gram-negative facultative anaerobe with a unipolar flagellum, prefers alkaline (pH 6–10), brackish (elevated sodium) environments. This chitinase-producing species comprises part of the autochthonous flora of brackish water environments where it is closely associated with zooplankton and other fauna having chitinous exoskeletons.<sup>11</sup> *V. cholerae* is a well-defined species based on biochemical tests and DNA homology studies,<sup>12</sup> but one that is not homogeneous with regard to the potential to cause epidemic human disease. Taxonomists currently recognize more than 200 serogroups of *V. cholerae*. Within the species, an important discrimination exists among strains with respect to the production of cholera enterotoxin (CT), O serogroup, and the potential for epidemic spread. Prior to 1992, only enterotoxigenic *V. cholerae* within the O1 serogroup were recognized as the etiologic agents of endemic and epidemic cholera. Within the O1 serogroup, there exist two main serotypes, Inaba and Ogawa, and two biotypes, classical and El Tor.<sup>12</sup> Whereas either biotype can cause the spectrum of clinical manifestations from asymptomatic infection to cholera gravis, the ratio of mild to severe cases is higher for the El Tor biotype. Characteristics that differentiate the El Tor biotype include a resistance to polymyxin B, ability to agglutinate chicken erythrocytes, and a susceptibility to specific typing phages. El Tor tend to be much hardier than classical biotype vibrios and survive better in the environment and in the intestine of humans. Even as *V. cholerae* El Tor has spread worldwide for almost 4 decades in the form of the seventh cholera pandemic, classical biotype *V. cholerae* persisted in the Ganges delta, along with El Tor, throughout much of this time.

*V. cholerae* O1 strains can shift between Inaba and Ogawa, with the change more often going from Ogawa to Inaba.<sup>12</sup> DNA sequence analysis of genes (*rfb*) encoding the O1 antigen reveals that the sequences for Inaba and Ogawa antigens are almost identical and that some serotype shifts are the consequence of minor alterations in the sequence of *rfbT*.<sup>13,14</sup>

Beginning in late 1992, large-scale epidemics of typical clinical cholera caused by a serogroup other than O1 were reported in India and Bangladesh,<sup>4,5</sup> marking the first time that epidemic disease was attributed to another serogroup. Molecular analysis of the causative agent, so-called O139 Bengal, reveals that it possesses the identical virulence attributes and other characteristics as *V. cholerae* El Tor (e.g., sequences encoding cholera toxin and toxin coregulated pili, resistance to polymyxin).<sup>12</sup> It appears that the epidemic O139 strain was derived by a deletion event in the genes that encode O1 of an El Tor strain followed by the acquisition of a large fragment of new DNA encoding O139. During 1993, O139 spread to multiple other Asian countries (e.g., Thailand,

Burma, Pakistan, China) and importations were also reported in the United States and United Kingdom. At this time, it was feared that these epidemiologic events might be the harbingers of an eighth cholera pandemic with O139 as the etiologic agent. However, in 1995 and 1996 the incidence of O139 diminished in the Indian subcontinent and this serogroup disappeared from several countries that it had invaded in the previous 2 years. Since O139 disease has become endemic in Bengal, health authorities for the past decade have maintained surveillance to see whether O139 disease resurges and spreads to other continents in pandemic form.

There also exist O1 and O139 strains that do not produce CT, do not cause cholera, and are not involved in epidemics. By contrast, there are sporadic *V. cholerae* strains of serogroups other than O1 or O139 that are associated with diarrhea or other clinical syndromes such as bacteremia; however, these other serogroups do not cause explosive epidemics or have pandemic potential.

## EPIDEMIOLOGY

### Incidence and Geographic Distribution

A defining feature of the epidemiology of cholera viewed from a global perspective is that, because of its pandemic nature, the disease ebbs and flows across vast geographic distances over time. The Ganges delta is the ancestral home of cholera, where it has persisted in the past in interpandemic periods as “Asiatic cholera.” As the seventh pandemic of

El Tor cholera has progressively disseminated since the early 1960s from its origin on the island of Sulawesi in Indonesia, it has become endemic in many areas where it first appeared in epidemic form. Thus, cholera is now endemic in the Philippines; in several countries in Southeast Asia; in multiple countries in sub-Saharan Africa; and (during the 1990s) in Peru, Ecuador, and a number of other Latin American countries.

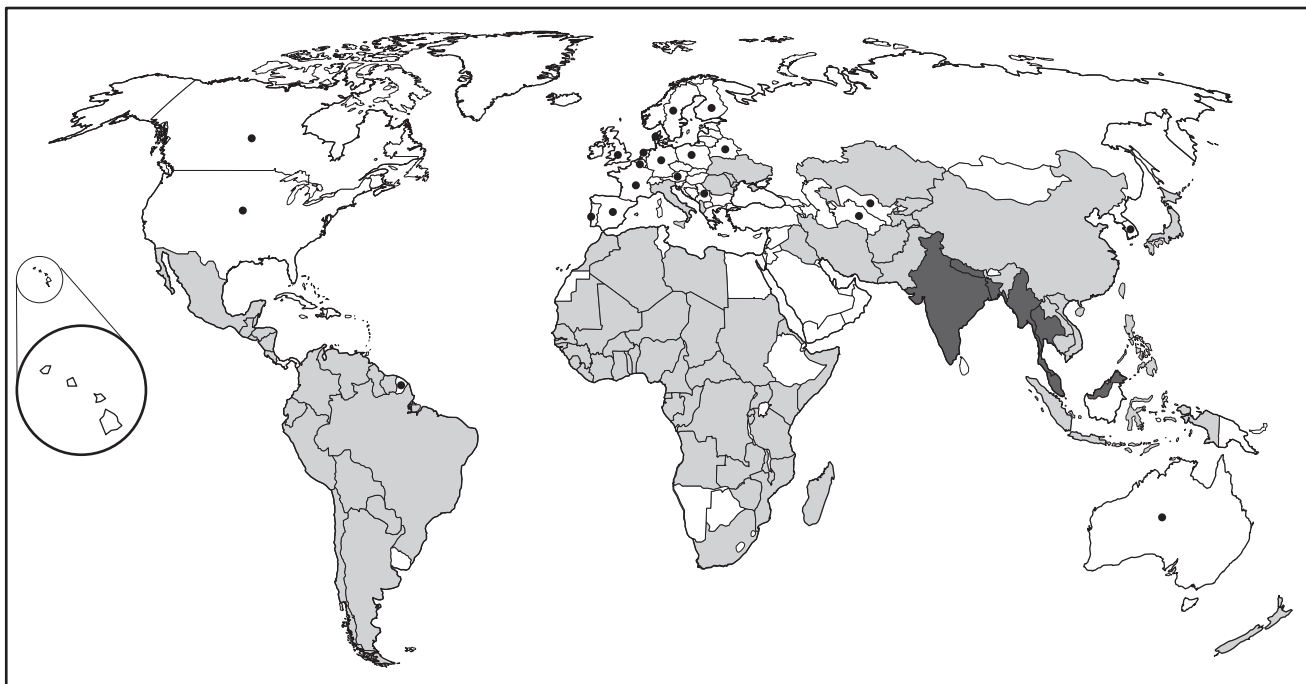

Typically, when cholera newly invades an immunologically naive population, the highest incidence is observed in young adult males. However, as the disease becomes increasingly endemic, the incidence increases in women and children; eventually, the peak incidence is found in young children.

### Seasonality

In most endemic areas, cholera exhibits a seasonal pattern with months of high and low incidence.<sup>15</sup> When a new cholera season begins, the disease typically appears simultaneously in multiple geographically separate foci. This pattern has also been seen as cholera invades new territory. For example, in 1991 when the cholera invasion of South America began with an explosive and extensive epidemic in Peru, large outbreaks appeared almost simultaneously in three distinct cities spanning a 900-kilometer stretch along the Pacific Coast.<sup>15</sup>

### Reservoirs of Infection

Since humans are the only known host of cholera and chronic carriers are extremely rare, it was previously assumed

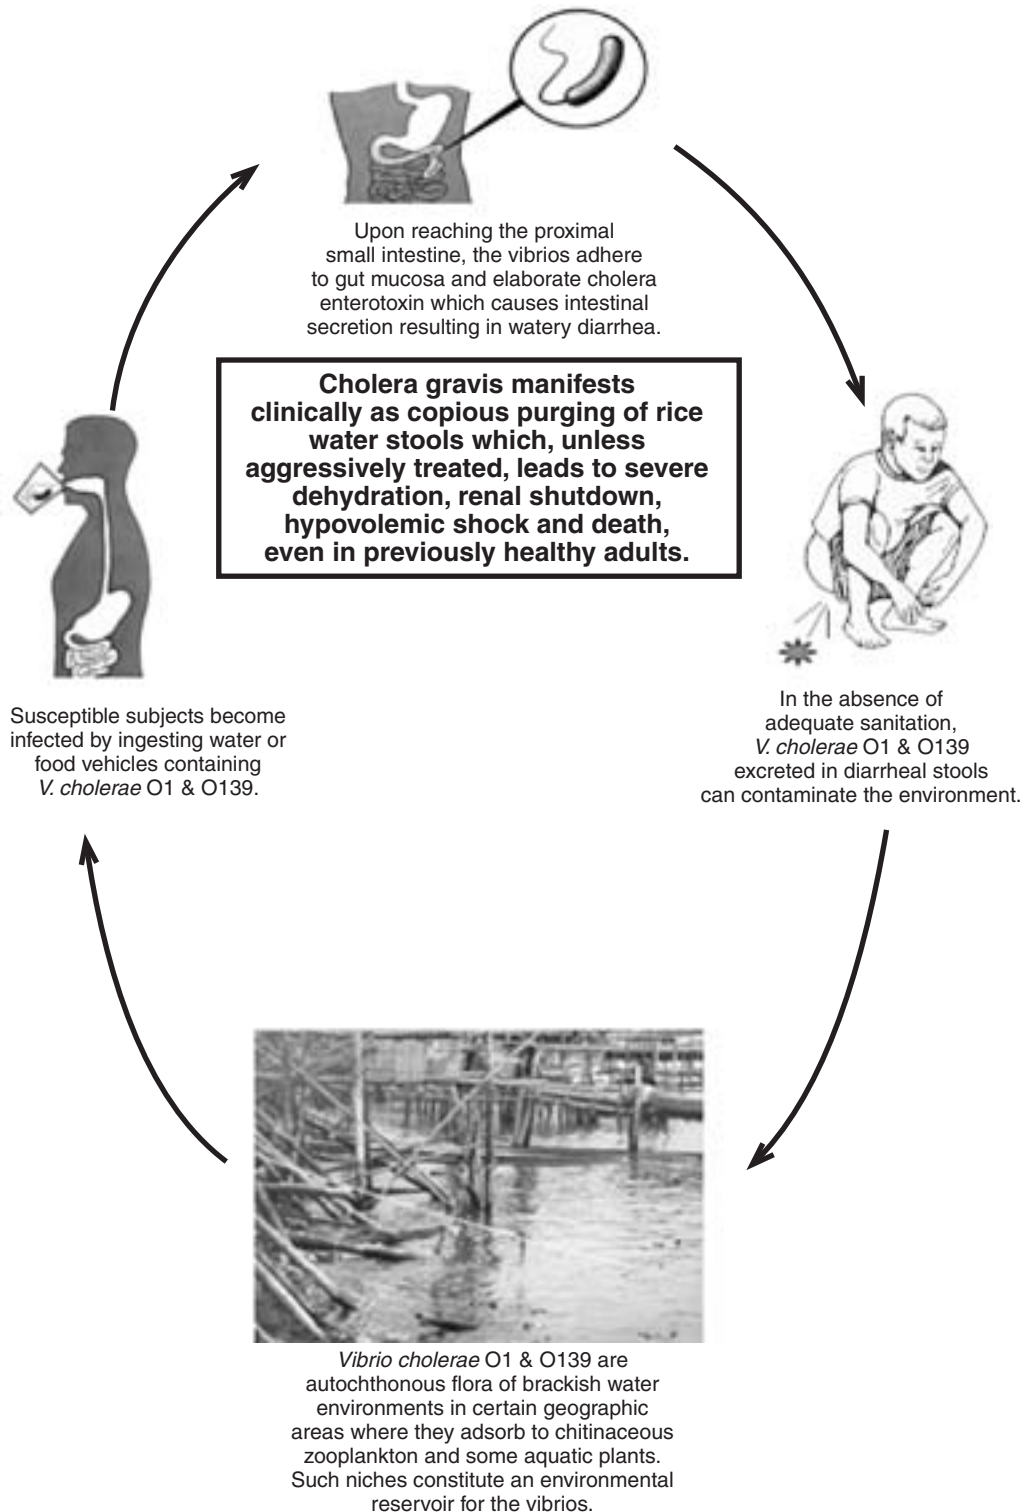

Cases of cholera since 1990

- *Vibrio cholerae* O1
- *Vibrio cholerae* O1 and/or O139
- Imported cases only

**Note:** Cholera likely occurs in some unshaded areas; shaded areas show those reported to the World Health Organization between 1990 and 2003.

that in endemic areas mild and asymptomatic infections serve as the reservoir to maintain the disease until the next cholera season when conditions would once again favor enhanced transmission. However, this explanation was unable to account for a number of the epidemiologic observations. Epidemiologists' views on what might comprise the reservoirs of cholera infection underwent radical change because of a series of events in the 1980s that occurred along the Gulf of Mexico Coast of the United States. The appearance of

a single case of cholera in Texas in 1973 in a fisherman caused by an unusual highly hemolytic El Tor Inaba strain<sup>16</sup> followed 5 years later by an outbreak of approximately two dozen cases of the identical strain in which poorly cooked seafood was incriminated as the vehicle,<sup>17</sup> led to the identification of an environmental focus of infection in the Gulf of Mexico. This El Tor Inaba strain was found to constitute autochthonous flora of the brackish waters of Gulf estuaries, where it was associated with shrimp and other crustacea eaten as local seafood.

Identification of a similar environmental focus of free-living enterotoxigenic *V. cholerae* O1 El Tor in Queensland, Australia, further supported the contention that, at least in some instances, brackish water environmental niches serve as the reservoir of *V. cholerae* O1.<sup>18</sup>

Colwell<sup>11</sup> reports that *V. cholerae* can enter a “viable but nonculturable” state that allows them to survive harsh environmental conditions by means of a kind of bacterial hibernation. When the toxigenic *V. cholerae* eventually encounter favorable conditions of temperature, salinity, pH, and so on, they can rejuvenate, regaining the potential to actively metabolize and grow.<sup>11</sup> These may also be the conditions under which zooplankton blooms occur.

### Modes of Transmission

Most of our knowledge about the vehicles of transmission of cholera stems from case-control investigations, which have demonstrated a number of distinct routes for waterborne transmission and an array of food vehicles.<sup>19,20</sup> Contaminated water remains an important vehicle of transmission in many parts of the world.<sup>20</sup> When El Tor cholera struck Latin America in explosive fashion in 1991, faulty municipal water and sewage systems, contaminated surface waters, and unsafe domestic water storage methods resulted in extensive waterborne cholera transmission.<sup>21,22</sup> Beverages prepared with contaminated water and sold by street vendors, ice, and even commercial bottled water have been incriminated.<sup>23</sup>

*V. cholerae* O1 may gain access to food in a primary manner, as by the natural association of vibrios with the chitinous exoskeletons of shrimp, crabs, and oysters in certain estuarine environments,<sup>11,17,24</sup> or food may be secondarily contaminated during preparation or handling.<sup>25</sup> The most commonly implicated food vehicle worldwide has been raw or undercooked seafood, including mussels, shrimps, oysters, cockles, clams, fish, salt fish, and ceviche (uncooked fish or shellfish marinated in lemon or lime juice).

Cooked grains, beans, and rice with sauces have also been repeatedly incriminated in cholera transmission. A small inoculum of enterotoxigenic *V. cholerae* introduced by an infected food handler into one of these types of food and stored without refrigeration can increase by several logs within 8 to 12 hours. In several instances, cholera has been transmitted by vegetables or fruit irrigated with raw sewage or doused with sewage to freshen them.<sup>26</sup>

During outbreaks or seasonal epidemics, cholera may be spread via multiple modes of transmission. Depending on local culture and customs, climate, and other factors, certain modes and vehicles of transmission predominate.<sup>27</sup> Finally, if pathogenic *V. cholerae* O1 and O139 persist in environmental reservoirs, then transmission across long distances can occur via the ballast water of large ships, as they intake ballast water in one port and discharge it prior to entering another port thousands of miles away.<sup>28</sup>

Epidemiologists, with few exceptions, recognize that person-to-person contact spread of cholera virtually never occurs. Transmission is essentially always via food or water vehicles.

### International Surveillance and Disease Notification

Since cholera was the disease for which modern public health surveillance and reporting was first organized, it bears

the code 001 in the international classification of diseases. Moreover, along with plague and yellow fever, by international convention, cholera is a notifiable disease. In 1994, 94 countries, the largest number ever, reported cholera to the World Health Organization (WHO), signifying the cumulative effect of epidemics in Africa, Asia, and Latin America. Nevertheless, for reasons involving trade, fear of food embargoes, and effects on tourism, many countries delay reporting cholera cases to the WHO or do not report at all. For example, from international health statistics in the late 1980s, Bangladesh would appear to have had little or no cholera. Yet at the same time as those “official” statistics were generated, large-scale field trials were carried out to evaluate cholera vaccines in which hundreds of confirmed cases were documented.<sup>29</sup>

### Host Risk Factors

Known host factors that greatly increase the risk of developing cholera gravis include blood group O,<sup>30</sup> hypochlorhydria,<sup>31,32</sup> and a lack of background immunity.<sup>33</sup> In both endemic and epidemic situations, persons of blood group O are clearly at much greater risk of developing cholera gravis than persons of other blood groups.<sup>30,34</sup> When cholera invades a new, immunologically naive population, persons with hypochlorhydria (e.g., with partial gastrectomy) have often been the index case.<sup>35</sup> In endemic areas, the highest incidence of cholera usually is seen in children 1 to 4 years of age. The age-specific incidence falls thereafter and the prevalence and geometric mean titer of serum vibriocidal antibody rise, as increasing immunity is acquired.<sup>36</sup> However, there is one interesting exception to this pattern: Women of childbearing age exhibit a high incidence.<sup>15</sup>

### Molecular Epidemiology

Molecular biologic techniques have been applied to analyze *V. cholerae* O1 and O139 strains in order to determine relationships and to deduce the origin or derivation of strains. The techniques include Southern blotting of restricted chromosomal DNA with specific probes, examination of restriction fragment length polymorphism (RFLP, ribotyping), pulsed-field gel electrophoresis (PFGE), multilocus enzyme electrophoresis (MEE, electrophoretotyping), comparison of DNA sequences, polymerase chain reaction methods, and full or partial genome sequencing.<sup>37–41</sup> Application of these molecular subtyping methods has revealed that there are four major clonal groups of *V. cholerae* O1 El Tor strains worldwide called: (1) seventh pandemic; (2) U.S. Gulf Coast; (3) Australia; (4) Latin America. The U.S. Gulf Coast and Australian strains, each representing an environmental reservoir, are closely related. The seventh pandemic and Latin American strains are also similar. It has also been shown that the O139 epidemic strains of 1992–1994 are closely related (indeed, virtually identical) to strains of the El Tor seventh pandemic clone.

### DISEASE

The incubation period is usually 18 to 40 hours but can be as short as 12 hours or as long as 72 hours, depending on the inoculum ingested and the susceptibility of the host.

**Table 21-1** Electrolyte Content of Cholera Stools in Older versus Younger Children

	Adult or Older Child	Young Child
Na <sup>+</sup>	135 mEq/L	100 mEq/L
Cl <sup>-</sup>	100 mEq/L	90 mEq/L
K <sup>+</sup>	15 mEq/L	30 mEq/L
HCO <sub>3</sub>	40 mEq/L	30 mEq/L

The first symptoms are a queasiness, nausea, and abdominal gurgling, followed by the onset of diarrhea. In severe cholera, the stools rapidly gain the character of rice water, become voluminous (up to 1.0–1.25 liters per hour in teenagers and adults) and are high in electrolyte content. Vomiting is common during the first 6 to 12 hours of clinical illness and thereafter disappears even though voluminous purging may continue.<sup>42</sup>

The electrolyte composition of cholera stools depends on the age of the patient and the purge rate. At peak purge, the isotonic “rice water” stools of adults and older children have high Na<sup>+</sup> (circa 135 mEq/L) and bicarbonate (circa 45 mEq/L) concentrations as shown in Table 21-1. In young children, the Na<sup>+</sup> concentration typically does not exceed 100 mEq/liter at peak purge.

As fluid and electrolyte deficits rapidly increase, signs of moderate and then severe dehydration appear. The patient has dry mucous membranes, an increased thready pulse rate, hypotension, sunken eyes, decreased skin turgor, decreased urine output, and thirst. Severely dehydrated patients have altered mental status, Kussmaul breathing, lethargy, stupor, and cold clammy skin. Cramping of peripheral skeletal muscles and of abdominal muscles consequent to acute potassium and calcium losses may cause extreme discomfort.

## Complications

Severe hypoglycemia from inadequate gluconeogenesis and exhaustion of glycogen stores is an uncommon complication seen in pediatric patients who manifest acute convulsions and even coma if serum glucose concentrations fall below 1 mmol/L.<sup>43</sup> In patients with severe dehydration and a marked decrease in renal perfusion, acute renal failure can occur. Very rarely, pulmonary edema can occur if large volumes of intravenous fluids without bicarbonate are rapidly infused in a patient with severe acidosis. In fact, this is a very rare complication and the opposite clinical situation—where there is a failure to administer intravenous fluids in volumes adequate to correct the extreme deficits encountered in the severe dehydration associated with cholera gravis—is much more frequent.

## PATHOGENESIS AND IMMUNITY

### Pathogenesis

There are few infections in which the molecular pathogenesis has been as well elucidated as cholera. One can think of *V. cholerae* O1 and O139 as complicated and elegant living delivery systems for cholera toxin, which is responsible for the severe purging characteristic of cholera gravis. Studies in

volunteers have shown that the ingestion of as little 5 µg of purified cholera enterotoxin induces a clinical syndrome that closely resembles the severe purging of cholera gravis.<sup>44</sup> Nevertheless, subsequent volunteer studies with *V. cholerae* O1 vaccine candidate strains harboring deletions in genes encoding the enzymatically active (A) subunit, both A and B (binding) subunits of cholera toxin or the entire cholera toxin virulence cassette (which encodes two other toxins and a minor fimbrial colonization factor) showed that some strains retained the ability to cause mild diarrhea and other gastrointestinal symptoms,<sup>45</sup> possibly via a mechanism that involves intestinal inflammation.<sup>46,47</sup> Moreover, whereas ingestion of purified cholera toxin alone may induce a syndrome of severe purging, the fully pathogenic vibrios that cause cholera in nature must carry multiple virulence factors that result in a stepwise progression ultimately resulting in severe diarrhea.

Following ingestion, pathogenic *V. cholerae* O1 or O139 must survive the formidable gastric acid barrier and pass through the pylorus to finally reach the proximal small intestine, the critical site of host-parasite interaction. Ingestion of 10<sup>6</sup> viable pathogenic *V. cholerae* by fasting North American volunteers results in neither infection nor diarrhea because the vibrios are destroyed by gastric acid.<sup>48</sup> In contrast, if 10<sup>6</sup> vibrios are administered with sodium bicarbonate buffer or food, cholera develops in approximately 90% of the volunteers.<sup>48</sup> Indeed, when administered with buffer, as few as 10<sup>3</sup> *V. cholerae* O1 El Tor cause diarrhea in approximately 67% of volunteers, although the stool volume is less than in subjects who ingest higher doses of vibrios.<sup>48</sup>

Once in the small intestine, the vibrios are believed to sense their environment by means of ToxR, a protein that is the product of a master regulatory gene, *toxR*.<sup>49</sup> Activation of *toxR* leads to expression of cholera toxin and toxin coregulated pili (TCP), the most important intestinal colonization factor,<sup>50,51</sup> as well as to the indirect activation (via *toxT*) of approximately 17 other genes involved with bacterial adaptation to survival in the human intestine. As neuraminidase and other vibrio enzymes break down the mucous barrier on the surface of the intestine, motility plays a critical role as the unipolar flagellum propels the organisms toward the enterocyte surface, attracted by chemotactins.

TCP constitutes the major intestinal colonization factor for *V. cholerae* O1 and O139.<sup>50,51</sup> The TCP of El Tor and O139 are genetically and antigenically identical but differ somewhat from TCP of classical biotype. The genes for TCP biogenesis are found within a 40-Kb *Vibrio* Pathogenicity Island (VPI). A mutant strain of *V. cholerae* O1, unable to express TCP, was unable to colonize the intestine of volunteers or to stimulate good vibriocidal antibody responses.<sup>52</sup> Surprisingly, although TCP must be expressed in order to elicit vibriocidal antibodies, specific antibody responses to TCP itself are not observed.<sup>53</sup>

The observation that early vaccine strains deleted of *ctxA* nevertheless were able to cause mild diarrhea, abdominal cramps, nausea, occasional vomiting, and low-grade fever<sup>54</sup> led to a search for possible accessory enterotoxins elaborated by *V. cholerae*. Two new toxins, Zonula occludens toxin (Zot)<sup>55</sup> and accessory cholera enterotoxin (Ace),<sup>56</sup> encoded by genes located in the cholera toxin virulence cassette were described. Subsequently, it was found that the *ctx* virulence cassette is actually the genome of a lysogenic filamentous bacteriophage (designated CTX-phi) and that Zot and Ace also play roles in phage morphogenesis.<sup>57,58</sup> CTX-phi comprises two regions,

core and RS2.<sup>57</sup> The former encodes cholera toxin and several proteins, including Ace, that participate in phage packaging and secretion. Genes within the RS2 region encode products required for replication (rstA), integration (rstB), and regulation of CTX-phi (rstR).<sup>59</sup> Notably, the attachment factor for the toxin-encoding phage is TCP.

## Immune Response

Following *V. cholerae* O1 infection, robust serum vibriocidal antibody responses and rises in immunoglobulin G (IgG) cholera antitoxin are observed.<sup>60,61</sup> Approximately 90% of complement-dependent vibriocidal antibodies are directed toward the O antigen with the remaining 10% to 15% of antibodies being against protein antigens. In immunologically primed individuals, strong SIgA intestinal antibody responses are recorded following cholera infection. However, significant rises in SIgA anti-LPS and antitoxin are surprisingly sparse in nonprimed individuals. The detection of gut-derived, trafficking IgA antibody-secreting cells that make specific antibody to LPS and CT antigens is a good measure of priming of the intestinal immune system.<sup>62</sup>

Whereas infection-derived immunity to cholera is believed to be mediated by intestinal mucosal SIgA antibodies, curiously, serum vibriocidal antibodies are the best correlate of protection.<sup>33,63</sup> These serum antibodies are presumed to be a proxy for the stimulation of intestinal antibodies.

Whereas high titers of specific vibriocidal antibodies appear after *V. cholerae* O1 infection, vibriocidal responses following O139 infection are weak and rather nonspecific.<sup>64</sup> A correlate of protection for O139 cholera has not yet been identified.

## DIAGNOSIS

Confirmation of *V. cholerae* O1 or O139 infection is achieved by isolation of the organism in stool culture, followed by biochemical tests and agglutination with specific antisera against O1 and O139.<sup>12,20</sup> Speciation of O1 is performed with Inaba and Ogawa typing antisera. Confirmation of the enterotoxigenicity of isolates is usually performed in reference laboratories by means of polymerase chain reaction (PCR) or DNA probes that detect cholera toxin genes or by immunoassays or bioassays that detect toxin.

Dark-field microscopy can provide a rapid presumptive diagnosis when used in conjunction with specific antisera. The motility of vibrios is seen to become immobilized in the presence of specific antibody. Various immunoassays that detect vibrio antigen have been used as rapid diagnostic tests.<sup>65–67</sup> A commercial colorimetric immunoassay directed against O1 and O139 antigens (Cholera and Bengal SMART, Direct Fluorescent Assay, New Horizons Diagnostics Corp.) greatly facilitates presumptive diagnosis.<sup>65,66</sup> PCR techniques can detect *V. cholerae* O1 and O139 in clinical specimens and in food even when viable vibrios are no longer present.<sup>12</sup>

## TREATMENT AND PROGNOSIS

There are three pillars to the therapy of patients with cholera: (1) aggressive rehydration therapy; (2) administration of antibiotics; and (3) treatment of complications. Aggressive rehydration by oral and intravenous routes to

repair fluid and electrolyte deficits and to replace the prodigious ongoing diarrheal losses is the cornerstone of therapy of cholera.<sup>68</sup> Appropriate antimicrobials are an important adjunct to fluid therapy, as they diminish the volume and duration of purging and rapidly curtail the excretion of vibrios, thereby diminishing the chance of secondary transmission. Finally, as rehydration therapy has become increasingly effective, patients surviving from hypovolemic shock and severe dehydration manifest certain complications, such as hypoglycemia, that must be recognized and promptly treated. If these fundamental guidelines are followed properly, case fatality, even during explosive epidemics in developing countries, can be kept below 1%.<sup>68,69</sup> On the other hand, failure to comply with these basic proven clinical rules can result in unacceptably high case fatality.<sup>3</sup>

## Fluid Therapy

Fluid therapy is divided into two phases: (1) *rapid* replacement of water and electrolyte deficits and (2) maintenance fluids to replace ongoing losses. Fluid and electrolyte deficits should be replenished as rapidly as possible (within 2–4 hours of initiation). Patients suffering from severe dehydration with or without overt shock usually must be rapidly rehydrated with intravenous fluids. Patients with cholera gravis generally require several liters of intravenous fluids to stabilize them to the point where oral rehydration can then begin; at the earliest opportunity, they are carefully weaned from intravenous fluids. In adults with cholera gravis, from 8 to 12 liters of intravenous fluids may be required before oral hydration alone can keep up with losses. Cholera patients with mild or moderate dehydration and moderate purge rates (<500 mL per hour) can usually be managed with oral rehydration alone.

## Intravenous Rehydration

The optimal intravenous solutions for treating cholera have a poly-electrolyte composition similar to that of the cholera stool. However, in fact, the most extensively used intravenous rehydration fluid worldwide for treatment of cholera is Ringer's lactate, because it is so widely available commercially. Ringer's lactate contains Na<sup>+</sup> 130 mEq/L, K<sup>+</sup> 4 mEq/L, Ca<sup>2+</sup> 3 mEq/L, Cl<sup>-</sup> 111 mEq/L, and lactate (precursor of HCO<sub>3</sub><sup>-</sup>) 29 mEq/L. Because the concentration of K<sup>+</sup> in Ringer's lactate is too low, supplemental K<sup>+</sup> must be administered either by adding a sterile KCl (or similar potassium salt) solution to the Ringer's solution to increase the concentration of K<sup>+</sup> to 15 to 20 mEq/L, or by initiating oral rehydration.

Aggressive rehydration with adequate volumes of fluid and appropriate electrolytes leads to rapid clinical improvement in the patient (e.g., stronger pulse, elevation of blood pressure, increase in skin turgor, and improved state of consciousness), which is also reflected in simple laboratory assays (e.g., fall in hematocrit and in plasma specific gravity). Once renal perfusion is re-established in the severely dehydrated patient, normal homeostatic mechanisms begin to combat acidosis and regulate serum electrolyte concentrations.

The volume of all diarrheal losses and vomitus must be measured in the patient with cholera. Once the patient has had replacement of his or her deficit and is in the stage of

maintenance therapy, fluid management is generally based on 4-hour periods. The total fluid losses during the previous 4-hour period constitute the volume of fluids that will be administered to the patient during the next 4 hours. As diarrheal losses begin to diminish, the 4-hourly replacement requirements will decrease accordingly.

### Oral Rehydration

Oral rehydration therapy was developed in the 1960s based on the discovery that glucose-mediated cotransport of sodium and water across the mucosal surface of the small intestine epithelium remains intact during cholera infection despite the effect of cholera toxin.<sup>70</sup> If the diarrhea is copious, large volumes of oral rehydration fluids must be ingested to keep up with ongoing losses.

The oral rehydration solution currently recommended by WHO is composed of Na<sup>+</sup> 90 mEq/L, Cl<sup>-</sup> 80 mEq/L, K<sup>+</sup> 20 mEq/L, citrate 30 mEq/L, and glucose 111 mmol/L. Packets containing sufficient salts and glucose to prepare 1 liter of rehydration solution are widely available in developing countries. Each packet contains 3.5 g of NaCl, 2.9 g of sodium citrate, 1.5 g of KCl, and 20 g of glucose. In some areas of the world, cereal-based oral rehydration solutions have become popular for the treatment of cholera.<sup>71,72</sup> The advantage of cereal-based oral rehydration solutions is that they provide multiple, actively transported substrates. However, some controlled trials have shown no advantage of cereal-based over glucose-based oral rehydration solutions.<sup>73</sup>

The regimen for calculating the amount of oral rehydration solution to be administered to replace ongoing losses differs by age. Since the Na<sup>+</sup> concentration in cholera stools is approximately 135 mEq/L in adults, one-and-a-half volumes of oral rehydration solution containing 90 mEq/L must be given for every volume of rice water diarrheal stool passed in order to adequately replace Na<sup>+</sup> losses. In contrast, in young children in whom the Na<sup>+</sup> concentration of cholera stools is only approximately 100 mEq/L, ongoing losses can be replaced on the basis of a 1:1 ratio of oral rehydration solution to volume of diarrheal stool. There is a practical limit to the volume of oral rehydration solution that can be consumed on an hourly basis; in older adults and teenagers, the upper limit is approximately 750 mL/hour.

Occasionally, there may be difficulty in promptly introducing an intravenous line in a cholera patient with severe dehydration. In such patients, the patient's head and upper torso should be elevated and a nasogastric tube should be inserted to initiate rehydration with oral rehydration solution until venous access can be obtained.

### Antimicrobial Therapy

Appropriate antibiotics significantly decrease the duration of diarrhea, the total diarrheal stool volume, and the duration of excretion of *V. cholerae*, and therefore serve as an important adjunct to rehydration therapy. Except for East Africa and a few other areas where tetracycline-resistant vibrios are endemic, tetracycline remains the drug of choice for all ages. The recommended pediatric dosage is 50 mg/kg/day in four divided doses for 3 to 5 days, whereas the regimen for

teenagers and adults is 500 mg four times daily for 3 to 5 days. Doxycycline has the advantage of being administered once daily in a dose of 4 to 6 mg/kg for children or 300 mg for teenagers and adults for 3 to 5 days. The short course of tetracycline therapy precludes staining of teeth and other adverse reactions encountered with long courses of this antibiotic.

In areas where tetracycline-resistant *V. cholerae* are prevalent or where antibiotics other than tetracycline are deemed preferable for the treatment of cholera in pediatric patients, alternative antimicrobial regimens that are usually effective include (5-day courses of therapy): erythromycin (pediatric dosage is 40 mg/kg/day in four divided doses; adult dosage is 250 mg four times daily); trimethoprim-sulfamethoxazole (pediatric dosage is 8 mg/kg/day of trimethoprim and 40 mg/kg/day of sulfamethoxazole in two divided doses; adult dosage is 160 mg of trimethoprim and 800 mg of sulfamethoxazole twice daily); furazolidone (pediatric dosage is 5 mg/kg/day in four divided doses; adult dosage is 100 mg every 6 hours); ampicillin (pediatric dosage is 50 mg/kg/day in four divided doses; adult dosage is 500 mg every 6 hours). Ciprofloxacin 250 mg once daily for 3 days is also a useful regimen.<sup>74</sup> In one randomized, controlled clinical trial, a single dose of azithromycin (20 mg/kg, maximum dose 1 g) was as effective as three days of erythromycin therapy (12.5 mg/kg every 6 hours).<sup>75</sup> Trimethoprim-sulfamethoxazole use should be avoided in areas where O139 is known to be prevalent, since *V. cholerae* O139 are typically resistant to this antimicrobial.<sup>76</sup> During epidemics in developing countries, single-day or single-dose antibiotic therapy (such as 1 g of ciprofloxacin or 300 mg of doxycycline for adults) may be necessary,<sup>77,78</sup> particularly if antibiotics are in short supply.

### PREVENTION AND CONTROL

Wherever human populations live under conditions of underdevelopment, characterized by a lack of treated water supplies and sanitation to remove human fecal wastes, the transmission of all enteric infections, including cholera, is favored. When an epidemic of cholera occurs, the first priority is to diminish case fatality by providing rehydration facilities, arranging rapid transport of patients to those facilities, and educating the population to promptly seek treatment when diarrhea begins. Prompt initiation of surveillance to identify the major foci of disease is critical in order to prioritize where scarce treatment and transport resources must be allocated. Mass media health messages are very useful to educate the population on the symptoms of cholera, advise where to seek treatment, and publicize what water sources or foods should be avoided and what practices should be discontinued or encouraged. In many instances, control of the epidemic can be achieved by incriminating the most important vehicles of transmission through epidemiologic case-control studies and then taking appropriate measures to eliminate consumption of the incriminated vehicle or to discontinue certain high-risk behaviors.

### Safe Water and Food

The threat of epidemic cholera often leads to emergency orders to boil all drinking water, advice that in many situations is impractical, expensive, and environmentally untenable.

Rather, chemical disinfection with sodium or calcium hypochlorite is a preferred alternative because it can be implemented at all levels from municipal or community reservoirs through distribution systems to household storage containers.<sup>79</sup> Hypochlorite-treated water retains residual free chlorine, so that if *V. cholerae* are introduced after treatment they cannot readily survive.

Defecation in the open air should be discouraged and emergency pit latrines should be built. Disinfectants such as cresol or lime should be used to disinfect stools and vomitus.

Simple modifications in food preparation practices markedly reduce the risk of cholera during epidemics. For example, the use of lemons, limes, and yogurt can acidify foods so that *V. cholerae* do not survive.<sup>80</sup>

### Chemoprophylaxis

In endemic areas or epidemic areas where secondary transmission within households is shown to be a frequent event, a short (3-day) course of tetracycline (or another cited antibiotic) administered to household contacts can diminish transmission within households.<sup>81</sup> However, such use of antibiotics must be strictly controlled because indiscriminate use in the community can rapidly lead to antibiotic resistance. This was the situation in Guayaquil, Ecuador, in 1991 following the introduction of cholera into that community. An attempt at mass chemoprophylaxis rapidly led to the appearance of *V. cholerae* O1 strains that had acquired resistance to tetracycline as well as several other antibiotics.<sup>82</sup>

### CHOLERA VACCINES

There are currently three licensed cholera vaccines available in various countries around the world. These include the old killed, whole-cell parenteral vaccine, the B subunit/killed whole-cell oral vaccine (BS/WCV),<sup>83,84</sup> and live oral *V. cholerae* O1 strain CVD 103-HgR.<sup>85,86</sup> The BS/WCV is marketed under the trade name Dukoral (SBL, Stockholm, Sweden), whereas CVD 103-HgR is marketed as Orochol or Mutacol (Berna Biotech, Berne, Switzerland). Neither the nonliving nor the live oral cholera vaccine is presently licensed in the United States. Since the old killed, whole-cell vaccine is reactogenic and confers only partial, short-term protection, there has been little enthusiasm on the part of public health authorities to recommend its widespread use. The two new oral vaccines have distinct advantages over the old parenteral vaccine. They are easy to administer and are more potent in stimulating local intestinal immune responses. These vaccines protect against cholera caused by *V. cholerae* serogroup O1 but not O139.

An advantage of the BS/WCV is its complete safety, even in immunocompromised subjects. A drawback to the BS/WCV is the need for two to three doses to confer protection. The nonliving vaccine elicits only modest serum vibriocidal responses but strong antitoxin responses. If time and circumstances allow pre-emptive immunization, the BS/WCV can be successfully delivered despite the need for two spaced doses.<sup>87</sup> Two randomized, controlled field trials assessed the efficacy of a two-dose regimen of the commercial formulation of the BS/WCV. Two doses of BS/WCV conferred 86% protection upon young adult Peruvian military personnel over approximately 5 months of follow-up.<sup>83</sup> A two-dose regimen

did not confer significant protection upon Peruvian civilians (children and adults) during a year of follow-up.<sup>84</sup> However, administration of a third dose conferred greater than 60% protection during a second year of follow-up.<sup>84</sup>

The safety and immunogenicity of single-dose live oral cholera vaccine strain CVD 103-HgR have been established in randomized, placebo-controlled, double-blind field trials in many developing and industrialized countries that have included thousands of young and elderly adults, children, and infants as young as 3 months of age.<sup>85,88–93</sup> The live vaccine stimulates stronger serum vibriocidal responses than the nonliving vaccine but lesser antitoxic responses. Multiple small clinical trials demonstrated that a single oral dose of CVD 103-HgR confers greater than 90% protection against moderate or severe cholera caused by *V. cholerae* O1 of either biotype or serotype<sup>85,86,94</sup>; the protective effect is evident as soon as 8 days after administration of vaccine.<sup>94</sup> A single-dose regimen of CVD 103-HgR did not confer long-term protection against El Tor cholera in an endemic area.<sup>95</sup> However, when used by the WHO in control of an epidemic of cholera in Micronesia (a situation where time and logistical constraints made it untenable to administer other than a single-dose vaccine), the single-dose live cholera vaccine exhibited 79% efficacy under field conditions.<sup>96</sup>

### Travelers

When cholera invaded Latin America in 1991, travel-associated cases of cholera increased markedly, in particular among U.S. travelers. Besides cholera in travelers, persons were infected in the United States when contaminated foods (e.g., seafood) were illegally brought into the United States by travelers and foodborne outbreaks related to air travel.<sup>97</sup> Cholera also became recognized as a notable cause of clinically moderate and severe diarrhea in ex-patriots who work and live in endemic areas of Latin America.<sup>98</sup>

# “Noncholera” *Vibrio* Infections

J. GLENN MORRIS, Jr.  
G. BALAKRISH NAIR

## AGENT

Cholera is a well-recognized (and highly feared) disease in tropical areas. As investigators in the early part of this century began to acquire an understanding of the “cholera bacillus” (*Vibrio cholerae*), it became apparent that these bacteria could be divided into two groups: those that agglutinated with serum from cholera patients (designated as O group 1 strains) and those that failed to agglutinate (designated as “nonagglutinating” or “noncholera” vibrios).<sup>1,2</sup> This latter group consisted primarily of environmental isolates that were thought to be nonpathogenic, although there was early speculation that they might be responsible for “paracholera” syndromes. Firm evidence of the pathogenicity of these strains did not emerge until the 1950s when the first outbreaks due to noncholera strains were identified and investigated. As data accumulated, it became increasingly clear that many of the strains were so distinct from *V. cholerae* as to constitute separate species.<sup>3,4</sup>

It is now recognized that within the species *V. cholerae* there are well over 200 O groups. Strains in serogroup O1 were regarded as the sole cause of epidemic cholera until 1992, when *V. cholerae* strains subsequently classified as O139 (syn. Bengal) first appeared and spread in epidemic form across the Indian subcontinent.<sup>5,6</sup> *V. cholerae* in serogroups other than O1 and O139 are generally defined as “noncholera” or “nonepidemic” vibrios. However, it should be recognized that serogroup is not a consistent marker for pathogenicity, as there are environmental *V. cholerae* O1 and O139 strains that do not carry the genes for standard virulence factors such as cholera toxin,<sup>7</sup> while strains in other serogroups (such as O37) have been found to be closely related genetically to epidemic O1 strains and have caused outbreaks of cholera-like illness.<sup>8,9</sup> Toxigenic strains of *V. cholerae* serogroup O141 have been associated with sporadic cholera-like diarrhea and bloodstream infections in the United States<sup>10</sup>; localized outbreaks of diarrheal illness have been caused by O10 and O12 strains in 1994 in Peru,<sup>11</sup> O6 and O14 strains in Khmer refugee camps in Thailand,<sup>12</sup> and O10 strains in India.<sup>13</sup> In general, however, non-O1/O139 *V. cholerae* strains have been associated with mild, sporadic illness, or with asymptomatic colonization.<sup>14</sup>

Fujino and coworkers first isolated what we now know as *V. parahaemolyticus* from clinical samples and from shirasu (dried sardines) associated with an outbreak of gastroenteritis that occurred in Osaka in 1950. Over the subsequent decade, many other outbreaks in Japan incriminated a halophilic, hemolytic gram-negative organism similar to that described by Fujino. The vehicles in these outbreaks were usually raw fish, shellfish, and cucumbers in brine. The names *Pasteurella parahaemolytica*, *Pseudomonas enteritis*, and *Oceanomonas parahaemolytica* were all suggested before taxonomic studies firmly placed the organism within the genus *Vibrio*.<sup>15,16</sup> The current serotyping scheme recognizes 75 combinations of O and K serotypes of *V. parahaemolyticus*. While early studies did not show a linkage between specific serogroups and virulence, a new *V. parahaemolyticus* clonal group that appears to have increased virulence has emerged during the past decade: these strains are found in a limited number of serogroups (O3:K6, O4:K68, O1:K25, O1:KUT) and appear to be responsible for a pandemic of *V. parahaemolyticus* gastroenteritis that has affected nine countries including the United States.<sup>17,18</sup>

In addition to *V. cholerae* and *V. parahaemolyticus*, nine other *Vibrio* species that can infect humans (or that have been isolated from humans) are now recognized. *V. fluvialis*,<sup>19,20</sup> *V. furnissi*,<sup>21</sup> *V. hollisae*,<sup>22</sup> and *V. mimicus*<sup>23,24</sup> have been associated primarily with diarrheal disease. *V. alginolyticus* and *V. damsela*<sup>22</sup> generally cause wound infections. *V. vulnificus*, initially described in 1979 as a “lactose-positive marine *Vibrio*,” is recognized as an important cause of septicemia in alcoholics and immunosuppressed hosts; cases have been reported primarily from Korea, Taiwan, and the Gulf Coast region of the United States.<sup>25–27</sup> A newly described biogroup of *V. vulnificus*, biogroup 3, has been implicated in serious wound infections associated with exposure to live tilapia in Israel.<sup>28</sup> Descriptions of infections with *V. cincinnatiensis*,<sup>29</sup> *V. carchariae*,<sup>30</sup> and *V. metschnikovii*<sup>31,32</sup> have been restricted to case reports, and the significance of their isolation from humans remains to be determined. Table 22-1 lists the *Vibrio* species associated with human illness, together with data on numbers of reported cases and deaths in the United States for 1999.<sup>33</sup> Numerous other *Vibrio* species (currently totaling at least 50) inhabit the marine environment, but are not known to be pathogenic to humans.

## EPIDEMIOLOGY

### Incidence

*V. parahaemolyticus* is the most commonly isolated noncholera vibrio. In Japan, it has traditionally been implicated as the cause of at least one-fourth of food-borne disease cases.<sup>16</sup> After having shown a decreasing trend in recent years, *V. parahaemolyticus* cases started to increase again around 1994 in Japan. Between 1996 and 1998, the number of cases more than doubled, with 12,346 cases in 850 incidents reported in 1998; this increase appears to be linked with the appearance of the new clonal group of pandemic *V. parahaemolyticus* strains in serogroups O3:K6, O4:K68, O1:K25, and O1:KUT.<sup>34</sup> Diarrheal cases attributed to strains in these groups have also been rapidly increasing in Bangladesh, India, Taiwan, and other southeast Asian countries since 1996, as well as in the United States.<sup>34–38</sup>

**Table 22-1** *Vibrio* Species Implicated as Causes of Human Disease and Number of Deaths Associated with Infection with These Species

<b><i>Vibrio</i> Species</b>	<b>Clinical Presentation</b>			<b>No. of Cases (No. of Deaths)*</b>
	<b>Gastroenteritis</b>	<b>Wound or Ear Infection</b>	<b>Septicemia</b>	
<i>V. cholerae</i>				
Epidemic (O1, O139)	++	(+)	—	5 (0) <sup>†</sup>
Nonepidemic	++	+	+	45 (0)
<i>V. mimicus</i>	++	+	—	10 (0)
<i>V. parahaemolyticus</i>	++	+	(+)	116 (1)
<i>V. fluvialis</i>	++	+	+	19 (0)
<i>V. furnissii</i>	++	—	—	1 (0)
<i>V. hollisae</i>	++	+	(+)	13 (0)
<i>V. vulnificus</i>	+	++	++	83 (31) <sup>‡</sup>
<i>V. alginolyticus</i>	—	++	—	28 (0)
<i>V. damsela</i>	—	++	—	2 (0)
<i>V. cincinnatiensis</i>	—	—	(+)	0 (0)
<i>V. carchariae</i>	—	(+)	—	0 (0)
<i>V. metschnikovii</i>	(+)	—	(+)	1 (0)

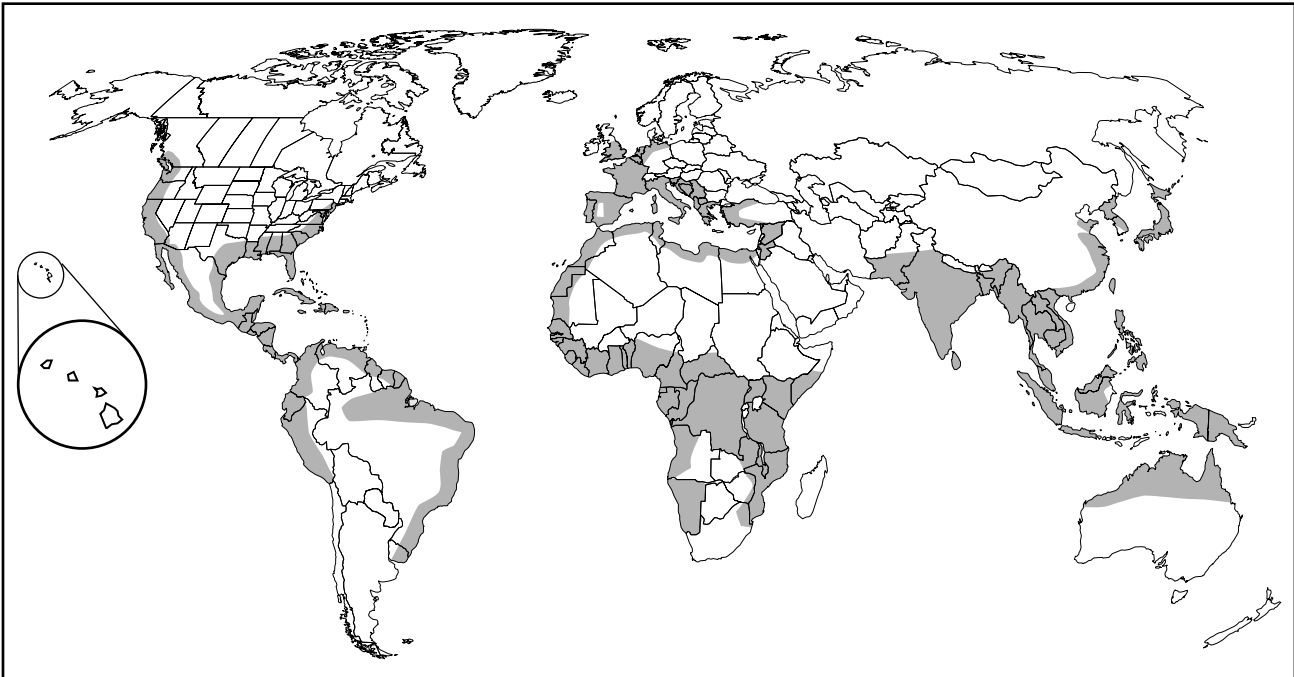

++, Most common clinical presentation; +, neither rare nor most common clinical presentation; (+), rare clinical presentation.

\*Data reflect *Vibrio* infections reported to the Centers for Disease Control and Prevention during 1999. Data are from the 24 states that reported cases; for many of these states, reporting of *Vibrio* infections is not routine, and consequently numbers may not reflect the true number of cases. Data were kindly provided by R. Tauxe, U.S. Centers for Disease Control and Prevention, Atlanta.

<sup>†</sup>Data include 4 cases associated with foreign travel.

<sup>‡</sup>The 31 reported deaths are from a group of 75 cases for which data on death were available.

From Morris JG Jr: Cholera and other types of vibrioses: A story of human pandemics and oysters on the half shell. Clin Infect Dis 37:272–280, 2003.

**Noncholera *Vibrio* infections**

- Endemic areas
- Cases less likely

*V. cholerae* in O groups other than O1 or O139 Bengal has been isolated from 2% to 3% of patients with diarrheal illness in tropical areas (including travelers).<sup>14</sup> As seen with other *Vibrio* species, isolation rates appear to be higher in coastal areas: an isolation rate of 16.4% was reported from Cancun, Mexico,<sup>39</sup> as compared with no isolations in a study in Mexico City.<sup>40</sup> In Calcutta, a cholera-endemic area, the isolation rate for nonepidemic strains of *V. cholerae* among patients hospitalized with diarrhea has been reported to vary between 2.7% and 4.9%, with no temporal clustering of any particular serogroup and no pronounced seasonality.<sup>41</sup>

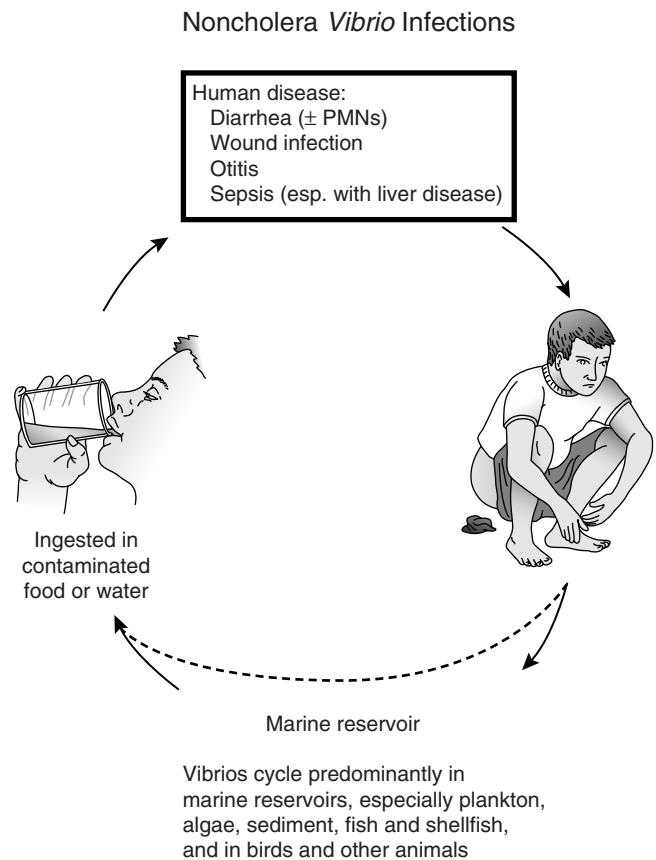

In a 13-year study in Florida,<sup>41</sup> *V. hollisae* was the third most common *Vibrio* species (after *V. parahaemolyticus* and *V. cholerae*) isolated from patients with diarrhea. Population-based data on rates of isolation of this and other *Vibrio* species from patients with diarrhea in tropical areas are limited; however, it is likely that they are responsible for substantively fewer cases of illness than are *V. cholerae* and *V. parahaemolyticus*. *V. vulnificus* is the most common cause of vibrio-associated sepsis in the United States; incidence in coastal areas has been estimated to be in the range of 0.5 cases/100,000 population per year.<sup>42,43</sup> While population-based data are lacking, incidence rates appear to be higher in Korea and Taiwan.<sup>26,44</sup>

### Carriage

Long-term human carriage of *Vibrio* species is unusual; chronic carriers do not appear to play a role in the epidemiology of the disease. However, short-term carriage or asymptomatic infections may be relatively common. From a cohort of 479 physicians attending a meeting in New Orleans who agreed to submit stool samples, 51 stool samples were positive for noncholera vibrios (*V. parahaemolyticus*, nonepidemic *V. cholerae*, *V. vulnificus*, *V. fluvialis*, and *V. mimicus*), of which 36 had been collected from individuals reporting no recent diarrheal illness.<sup>45</sup> In a large study conducted in Iran in 1971, 1.6% of pilgrims returning from Mecca were estimated to be carriers of noncholera *V. cholerae* (compared with 0.015% of persons leaving for Mecca). Isolations of this organism from stool cultures obtained from the contacts of these pilgrims increased over the following 6 months and decreased thereafter. Of these contacts, 60% reported diarrheal illness.<sup>46</sup> In a study in Calcutta, 15.3% of family contacts of *V. parahaemolyticus* diarrhea cases were found to be carrying the organism, with excretion continuing for up to 5 days.<sup>47</sup> Carriage of *Vibrio* species by wild and domestic animals is also well described: nonepidemic *V. cholerae* has been isolated from dogs in Calcutta<sup>48</sup>; from cows, goats, dogs, and chickens in India<sup>49</sup>; from ducks in Denmark<sup>50</sup>; from seagulls in England; and from horses, lambs, and bison in Colorado.<sup>51</sup>

### Transmission

Transmission pathways are shown in the following "life cycle." The marine or estuarine environment serves as the primary reservoir for these organisms. However, there is also the possibility of secondary contamination of food and water sources by feces from infected humans and animals.

In temperate regions, virtually all cases can be linked back to seafood, particularly raw or undercooked seafood.<sup>42</sup> Raw oysters are commonly implicated in transmission; while U.S. *V. cholerae* and *V. vulnificus* cases have always been significantly associated with raw oyster consumption,<sup>52,53</sup> there were major U.S. *V. parahaemolyticus* outbreaks linked with oysters in 1997 (Washington State) and 1998 (Texas, New York, Connecticut, and Washington State).<sup>54</sup> The pattern is less clear in tropical areas, possibly because of the increased risk of fecal contamination of food and water sources, or cross-contamination of foods by seafood vehicles. For example, in the previously noted study in Cancun,<sup>39</sup> home-prepared gelatin was the only statistically significant risk factor identified in a case-control study; however, the organism was isolated from 86% of untreated well water samples, 92% of sewage samples, and 21% of seafood samples. Similarly, a waterborne outbreak of noncholera *V. cholerae* occurred in the Sudan in 1968 due to contamination of surface water next to a well.<sup>55</sup>

### Ecology/Distribution/Seasonality

Vibrios are ubiquitous in the marine environment. While most are halophilic (i.e., require salt for growth), *V. cholerae* can grow in freshwater, and has been isolated from freshwater lakes.<sup>56,57</sup> In temperate climates, counts of vibrio bacteria vary seasonally: in the summer (when water temperatures exceed 20°C), vibrios can easily be isolated from water, suspended particulate matter, plankton, algae, sediment, fish, and shellfish; during the winter months, they decline markedly in

number and are found primarily in sediments.<sup>15,58</sup> Among other possible natural reservoirs, egg masses of the nonbiting midge *Chironomus* spp (Diptera) have recently been shown to harbor *V. cholerae*.<sup>59</sup> Vibrio counts are independent of the level of fecal coliforms; that is, these are naturally occurring, free-living organisms that can be present in “pristine” waters that are free of fecal contamination.

Vibrio counts in oysters tend to be particularly high, with numbers of *V. parahaemolyticus* and *V. vulnificus* that may be 100 times higher than the surrounding water.<sup>58</sup> In a survey conducted by the Food and Drug Administration (FDA), non-O1 *V. cholerae* could be isolated from 14% of randomly selected oyster shell stock.<sup>60</sup> Studies along the Gulf Coast and in Chesapeake Bay indicate that virtually all summer-harvested oysters carry *V. vulnificus* and/or *V. parahaemolyticus*, with counts that can exceed 10<sup>4</sup>/g of oyster meat.<sup>54,58,61</sup> *V. cholerae* and *V. vulnificus* can shift to a “viable but nonculturable” form, which may permit them to survive for extended periods in the environment under adverse conditions.<sup>62–64</sup> *V. cholerae* (and possibly other species) also have the ability to acquire a “rugose” morphology, associated with the production of a surface polysaccharide that promotes cell aggregation and provides protection to the organism by formation of biofilm-like masses of cells.<sup>65</sup>

As noted previously, vibrios are ubiquitous: they can be found in marine environments, estuaries, and freshwater throughout the world. Human illness due to vibrios shares a similar distribution, although patterns of illness vary from region to region, depending, in part, on cultural factors. In Japan, where consumption of seafood (including raw and undercooked seafood) is relatively common, *V. parahaemolyticus* accounts for a large proportion of food-borne illness. *V. vulnificus* has emerged as a significant health problem in Korea and Taiwan, linked again with consumption of raw or undercooked seafood.<sup>26,44</sup> In the United States, where vibrio infections appear to be less common, outbreaks and sporadic cases are concentrated along the Atlantic, Gulf, and Pacific coastlines.

In temperate areas illness tends to follow a seasonal pattern,<sup>42</sup> which can be correlated with levels of the causative organism in the environment. There have been suggestions that increasing water temperatures in coastal areas in the United States (possibly related to global warming) have served as a co-factor in the increasing incidence of *V. parahaemolyticus* in this country.<sup>66</sup> Seasonality is less apparent in tropical areas.

### Host Factors

In cases of vibrio gastroenteritis, factors such as sex, race, or blood group have not shown any consistent correlation with disease. The median age of persons with vibrio gastroenteritis varies with geographic location. In Cancún, Mexico, for example, children less than 1 year of age were at highest risk of infection with nonepidemic *V. cholerae*,<sup>39</sup> whereas in Bangladesh and Thailand cases tended to occur in older children and adults. In a survey of 14 sporadic nonepidemic *V. cholerae* infections in the United States,<sup>52</sup> the median patient age was 45, which may reflect the older age of the population that consumes raw oysters. Factors that decrease gastric acidity may increase the risk of infection.

Host factors play a much more important role in the epidemiology of sepsis due to *Vibrio* species. Virtually all patients with sepsis due to *V. vulnificus* and nonepidemic *V. cholerae*

have an underlying chronic medical illness.<sup>25–27,42,53,67,68</sup> Those with liver disease, such as alcoholic cirrhosis or hemochromatosis, are especially at risk. Based on the number of cases reported to the Florida Health Department between 1981 and 1992, the annual rate of illness from *V. vulnificus* infection in adults with self-reported liver disease in Florida who ate raw oysters was 7.2 per 100,000 adults, 80 times the rate for adults without known liver disease who ate raw oysters (0.09 cases per 100,000 population).<sup>53</sup> The risk of sepsis due to *V. parahaemolyticus* also appears to be increased by the presence of underlying chronic illness, although the association does not appear to be as strong as that seen with *V. cholerae* and *V. vulnificus*. Again, there are suggestions that risk is increased in patients with decreased gastric acidity.

### DISEASE

Primary clinical presentations vary by species and may include gastroenteritis, wound and ear infections, and septicemia.

*Vibrio*-associated gastroenteritis is similar to that seen with other enteric pathogens, with patients reporting diarrhea, abdominal pain, and, to a lesser degree, nausea and vomiting. In studies of sporadic noncholera *V. cholerae* cases identified retrospectively on the basis of stool cultures, illness has been relatively severe. Among 14 sporadic cases identified in a study in the United States,<sup>52</sup> the median duration of illness was 6.4 days. All of these patients had diarrhea, 71% had fever, but only 21% had nausea and vomiting. One-fourth of these patients had bloody diarrhea. Experimental infections in normal, healthy volunteers<sup>69</sup> and cases identified through outbreak investigations<sup>70,71</sup> have been associated with less severe disease, with median durations of illness ranging from 12 to 24 hours. The incubation period in outbreaks ranged from 12 to 24 hours; the median incubation period in volunteers<sup>69</sup> was 10 hours (range, 5.5 to 96 hours).

*V. parahaemolyticus* produces a similar spectrum of gastrointestinal illness. In a summary of clinical data from 202 patients with *V. parahaemolyticus* gastroenteritis that were reported to the Centers for Disease Control and Prevention (CDC) between 1973 and 1998, manifestations included diarrhea (98%), abdominal cramps (89%), nausea (76%), vomiting (55%), and fever (52%).<sup>35</sup> In both the United States and Japan, illness tends to be mild, with a median duration (in U.S. foodborne outbreaks) of 2.4 days.<sup>35</sup> Bloody stools were noted in 29% of *V. parahaemolyticus* cases reported to the CDC.<sup>35</sup> There are also rare reports of more severe illness: a dysentery-like syndrome may occur in association with infection,<sup>72,73</sup> hypotension and shock occurred in three of five *V. parahaemolyticus* cases in one outbreak in Great Britain, and there were 20 deaths among the 272 patients involved in the Japanese outbreak where *V. parahaemolyticus* was first identified.<sup>15</sup> The incubation period for *V. parahaemolyticus* generally ranges from 4 to 48 hours, with most illness occurring 12 to 24 hours after exposure. *Vibrio* species have been isolated from seawater-exposed wounds<sup>14,42</sup> and have been implicated as a cause of otitis and, rarely, pneumonia associated with near-drowning episodes.<sup>14</sup> While infection can occur in normal hosts, complications, including sepsis, are more likely in persons who are immunocompromised or have chronic underlying illnesses.<sup>42</sup>

Septicemia, due primarily to encapsulated strains of *V. vulnificus* and *V. cholerae*, occurs almost exclusively in persons

who have underlying liver disease, are alcoholic, diabetic, or in some way immunocompromised.<sup>25–27,67,68</sup> One-third of patients with *V. vulnificus* septicemia present in shock.<sup>25–27</sup> Thrombocytopenia is common, and there is often evidence of disseminated intravascular coagulation; gastrointestinal bleeding is not infrequent. The mortality rate is greater than 50%, with mortality exceeding 90% among patients who become hypotensive within the first 24 hours of hospitalization. Three-fourths of patients with *V. vulnificus* septicemia have characteristic bullous skin lesions<sup>3,25–27</sup>; identification of these skin lesions in the appropriate epidemiologic setting should prompt aggressive, specific therapy for this pathogen. While there are fewer data on patients with *V. cholerae* septicemia, the clinical presentation is comparable to that seen with *V. vulnificus* (although skin lesions do not appear to be as prominent); the mortality rate in a recent case series from Taiwan was 47%, with a rate in excess of 60% noted in an older U.S. series.<sup>67,68</sup>

## **PATHOGENESIS**

It is likely that nonepidemic *V. cholerae* strains cause gastroenteritis through a number of different mechanisms, analogous to the multiplicity of mechanisms described for diarrheagenic *Escherichia coli*. Some *V. cholerae* strains outside of O groups 1 and 139 Bengal carry the genes for and produce cholera toxin (CT).<sup>8,63</sup> In one study in Bangladesh, CT-producing strains were isolated from 29% of cases of sporadic non-O1 *V. cholerae* gastroenteritis; patients infected with these strains had more severe illness, with greater weight loss, a significantly higher specific gravity on admission, and more prolonged and profuse diarrhea.<sup>74</sup> Most other studies, however, show that the production of CT is relatively uncommon among clinical isolates of nonepidemic serotypes of *V. cholerae*.<sup>14,75</sup>

A subgroup of *V. cholerae* strains produces a heat-stable enterotoxin (designated NAG-ST<sup>76</sup>) that closely resembles the heat-stable enterotoxin of enterotoxigenic *E. coli*. Volunteer studies, as well as epidemiologic studies of outbreak and sporadic cases of nonepidemic *V. cholerae* disease, suggest that these strains, tentatively designated enterotoxigenic *V. cholerae*, are a cause of diarrheal disease in humans.<sup>12,68</sup> Recently, the presence of a toxin gene cluster related to the family of RTX toxins was shown in several environmental isolates of *V. cholerae*, including non-O1 and O1, CT-negative strains. The RTX toxins genes encode a product that is responsible for a cytotoxic activity observed when mammalian cells are exposed to *V. cholerae* cells, suggesting that this toxin could be responsible for some of the pathogenic properties of the nonepidemic strains of *V. cholerae*.<sup>77</sup> While this and a number of other virulence factors have been proposed for nonepidemic *V. cholerae* strains,<sup>78</sup> the role of these factors in disease causation is not completely clear. In studies in volunteers,<sup>68</sup> two out of three nonepidemic *V. cholerae* strains tested did not cause human disease, suggesting that many, if not most, of the strains outside of known pathogenic subgroups are nonpathogenic commensals.

The pathogenicity of *V. parahaemolyticus* isolates has traditionally been correlated with the production of the thermostable direct hemolysin (Vp-TDH), which is responsible for the beta hemolysis seen when these isolates are plated on Wagatsuma agar.<sup>15,79,80</sup> Original studies in Japan showed that this phenomenon, named the Kanagawa phenomenon after the prefecture in Japan where it was discovered, was present in 96% of clinical isolates but in only 1% of environmental

isolates. Volunteer studies also demonstrated the importance of Vp-TDH: Kanagawa-positive strains produced diarrhea whereas doses of up to 10<sup>9</sup> Kanagawa-negative strains failed to do so in 15 volunteers.<sup>81</sup> Furthermore, studies with isogenic mutants have shown that deletion of the Vp-TDH gene results in loss of enterotoxic activity in laboratory models (Ussing chamber and rabbit ileal loop assays).<sup>82</sup>

A second group of hemolysins, known as Vp-TDH-related hemolysins, or Vp-TRH, can be found in certain clinical isolates, especially those that are Kanagawa-negative.<sup>83–85</sup> These hemolysins are genetically related to Vp-TDH (they share around 70% sequence homology) but are more diverse (less than 2.8% divergence among most Vp-TDH vs. 16% between two subgroups of Vp-TRH). Studies of *V. parahaemolyticus* from the west coast of the United States and from Thailand have linked clinical illness with isolation of urease-positive, Kanagawa-negative strains from stool cultures.<sup>86,87</sup> These strains, in turn, have been shown almost always to carry the *tdh* gene.<sup>88,89</sup> Screening for urease production may permit identification of a subset of *V. parahaemolyticus* isolates that are Kanagawa-negative but are nonetheless virulent in humans. Whole genome sequence comparisons between *V. cholerae* and *V. parahaemolyticus* show that the two organisms use distinct mechanisms to establish infection with the genes of a type III secretion system (TTSS) being identified in the genome of *V. parahaemolyticus* but not *V. cholerae*.<sup>90</sup> The TTSS is a central virulence factor of diarrhea-causing bacteria such as shigella, salmonella, and enteropathogenic *E. coli*, which cause gastroenteritis by invading or intimately interacting with intestinal epithelial cells. Infection with *V. parahaemolyticus* results in B-cell responses and an acute inflammatory response that is self-limiting and less severe than that observed in patients with shigellosis but more severe than that seen in patients with cholera.<sup>91</sup>

Encapsulation appears to be a key virulence factor for strains which cause septicemia.<sup>92,93</sup> All *V. vulnificus* strains can produce a polysaccharide capsule. A majority of nonepidemic strains of *V. cholerae* also produce a capsule, with the degree of encapsulation correlating significantly with the risk of sepsis.<sup>94</sup> *V. cholerae* O1 strains (i.e., epidemic cholera strains) are not encapsulated and have not been associated with septicemia. Interestingly, *V. cholerae* O139 Bengal strains are encapsulated<sup>95</sup> and do appear to be able to cause septicemia in susceptible hosts. Encapsulation provides vibrios with protection against serum bactericidal activity and allows bacteria to resist opsonization and phagocytosis. Antibodies directed against the capsular polysaccharide are protective in animal models.<sup>96</sup>

## **DIAGNOSIS**

Although some *Vibrio* species will grow on media routinely used for isolating stool pathogens, identification is often difficult. A selective medium made with thiosulfate, citrate, bile salts, and sucrose (TCBS agar) has become the standard medium used in microbiology laboratories for the isolation of these organisms. With the exception of a few strains of *V. hollisae*, all pathogenic vibrios will grow on this medium, producing colonies that are yellow (sucrose fermenters such as *V. cholerae*) or blue-green (nonsucrose fermenters such as *V. parahaemolyticus*). Isolates from wounds and blood will grow on any standard culture medium, including blood agar.

**Table 22-2** Tests for Differentiation of Selected *Vibrio* Species

Test	<i>V. cholerae</i> O1 and Non-O1	<i>V. mimicus</i>	<i>V. parahaemolyticus</i>	<i>V. fluvialis</i>	<i>V. furnissi</i>	<i>V. hollisae</i>	<i>V. vulnificus</i>

Growth on TCBS	Y	G	G	Y	Y	G/–	G/Y

+, most strains positive; –, most strains negative; +/– or –/+, variable reaction (predominant reaction shown as the numerator); ( ), delayed reaction; G, green colonies; R, resistant; S, susceptible; Y, yellow colonies; TCBS, thiosulfate citrate bile salts sucrose agar.

\*Recent cotrimoxazole-resistant isolates in Calcutta also show resistance to pteridine.

From Janda JM, Powers C, Bryant AG, et al: Current perspectives on the epidemiology and pathogenesis of clinically significant *Vibrio* species. Clin Microbiol Rev 1:245–267, 1988.

Confirmation of the genus and identification of the species can be accomplished using standard biochemical panels (Table 22-2). It is important to remember that many vibrios are halophilic: the addition of 1% NaCl to growth media is often necessary to prevent false-negative reactions. When examining environmental samples, especially water samples, concentration procedures or selective enrichment broths may be needed.

Serotyping<sup>97</sup> is available for *V. cholerae* through the National Institute of Health, Tokyo, and may prove useful in analysis of outbreak-related strains. PCR and probe-based methods for identification of critical genes in many of these species are increasingly available on an experimental basis.<sup>98–100</sup> Similarly, there are increasing data on typing of strains by pulsed-field gel electrophoresis (PFGE) and multilocus sequence typing (MLST).<sup>101</sup>

## TREATMENT AND PROGNOSIS

### Treatment

As in any diarrheal disease, volume repletion is the most important element of therapy in patients with vibrio

gastroenteritis. Antimicrobial therapy in cholera has been shown to reduce the duration of diarrhea and the excretion of vibrios. While there are no controlled trials of therapy in vibrio gastroenteritis, the use of antimicrobial therapy in more severe cases would appear to be reasonable. Based on in vitro susceptibility data (and data from clinical trials in cholera) tetracycline or ciprofloxacin appear to be the drugs of choice for therapy.

Wound infections require appropriate débridement and antimicrobial therapy; again, tetracycline or ciprofloxacin appear to be reasonable choices. For patients with septicemia, rapid initiation of antimicrobial therapy is critical, with studies suggesting that prognosis is worsened when therapy is delayed.<sup>25</sup> As with any patient with septicemia and shock, supportive care (ideally in an intensive care unit setting) is essential. Although no controlled trials are available, a combination of minocycline (100 mg q12h po) and cefotaxime (2.0 g q8h iv) or use of a “newer” fluoroquinolone has been recommended for treatment of sepsis caused by *V. vulnificus*,<sup>102,103</sup> and would appear to be reasonable in management of sepsis caused by other *Vibrio* species.

It has been shown in animal models that hyperimmune serum directed against the *V. vulnificus* capsular polysaccharide

does protect against death in animal models, even when administered after onset of symptoms.<sup>96</sup> However, both *V. vulnificus* and nonepidemic *V. cholerae* have a large number of different capsule types, with preliminary data suggesting that antisera directed against one capsular type is not cross-protective; the resultant need for a multivalent product will make it more difficult to produce a useful therapeutic immunoglobulin.

## Prognosis

The prognosis in vibrio gastroenteritis is excellent, with virtually all patients showing a complete recovery within a matter of days. As previously noted, unexpectedly high rates of mortality have been reported in some *V. parahaemolyticus* outbreaks. The reasons for this are not well understood, although there are anecdotal reports of cardiac arrhythmias and sudden death in persons infected with *V. parahaemolyticus*.

The prognosis for patients with *V. cholerae* or *V. vulnificus* septicemia is much more guarded. Mortality rates among these patients exceed 50%, with survivors often having long-term disability related to multiorgan system failure and the consequences of prolonged hospitalization in an intensive care unit.

## PREVENTION AND CONTROL

Given the ubiquitousness of this organism in nature, total prevention is unlikely so long as people eat raw or undercooked seafood. Risks can be reduced by adhering to proper food-handling techniques, including techniques to minimize cross-contamination within kitchens and prevent growth of bacteria in food vehicles. Provision of safe supplies of food and water (i.e., with minimal fecal contamination) is essential, particularly in developing countries. No vaccines are currently available for these pathogens; vaccination would also be of uncertain utility, given the relative infrequency (and generally self-limited nature) of most of these infections.

# Enteric *Clostridium* Infections

JONATHAN P. MOORMAN  
DAVID A. BOBAK

## INTRODUCTION

Diarrheal diseases in developed and developing countries are significant causes of morbidity and mortality and are caused by a variety of microbial pathogens.<sup>1-3</sup> During the past 25 years, *Clostridium difficile* has emerged as the most important pathogen causing antibiotic-associated diarrhea and colitis. *Clostridium difficile* is a well-described pathogen in the nosocomial setting and is now recognized as the major cause of nosocomial diarrhea in the United States.<sup>4,5</sup> There is evidence that this organism may be a significant cause of community-acquired diarrhea as well.<sup>6-8</sup> Because of a paucity of clinical studies, however, the incidence of *C. difficile* infections in developing countries is not entirely known. It appears likely, though, that *C. difficile* is at least as significant a cause of antibiotic-associated and nosocomial diarrhea in tropical countries as in more well-studied European and American populations. For example, reports from India, Bangladesh, Indonesia, Brazil, and Greece indicate that a significant proportion of antibiotic-associated diarrhea is caused by *C. difficile*.<sup>9-13</sup> The liberal use of nonprescription antibiotics in developing countries undoubtedly contributes to the emergence of such infections.<sup>1</sup>

The clinical syndrome of diarrhea and pseudomembranous colitis in association with antibiotic administration was first noted in the 1950s. However, the causative agent was originally believed to be *Staphylococcus aureus*, and it was not until the 1970s that *C. difficile* was definitively implicated in the pathogenesis of antibiotic-associated diarrhea and pseudomembranous colitis (PMC).<sup>14,15</sup> *Clostridium difficile* infections comprise a spectrum of disease that ranges from asymptomatic carriage to severe diarrhea, PMC, toxic megacolon, and death. A large number of studies during the past 20 years have determined the key pathophysiologic conditions that lead to *C. difficile*-induced diarrhea and colitis: (i) an altered or suppressed colonic bacterial flora, usually secondary to antibiotic administration or abdominal surgery, and (ii) acquisition of an enterotoxin-producing strain of *C. difficile*. Currently, treatment involves eradication of the organism with antibiotics. Future therapies, however, may well involve treatments that will interfere with colonization by the organism or inhibit the unique mechanism of action of the enterotoxin.

## AGENT

*Clostridium difficile* is a ubiquitous, spore-forming, gram-positive, anaerobic bacillus. The organism was originally isolated from the meconium and stools of newborns by Hall and O'Toole in 1935.<sup>16</sup> Although *C. difficile* was found to produce a cytotoxin in culture, the fact that the organism could be isolated from the stools of healthy infants led to the general opinion that *C. difficile* was not a significant pathogen. This conviction was held until the 1970s, when several lines of evidence pointed to a role for toxigenic *C. difficile* in clindamycin-associated colitis in patients and experimental animals.<sup>14,17</sup>

*Clostridium difficile* is widespread in the environment and can be isolated from the stools of a large variety of animals.<sup>18</sup> Animals are not considered to be an important source of exposure for humans, however. *Clostridium difficile* was originally named *Bacillus difficilis*,<sup>16</sup> a tribute to the difficulty encountered in initial attempts to culture the organism. Currently, numerous anaerobic selective culture systems based on an egg yolk agar base medium have successfully been used.<sup>19,20</sup> Colonies of *C. difficile* are flat, yellow, and surrounded by a yellow halo in the medium; Gram stains show a typical gram-positive, spore-forming bacillus. In addition to selective culture and morphology, the organism can be further analyzed and identified using gas chromatographic techniques.

*Clostridium difficile* produces at least two distinct exotoxins: toxin A and toxin B. Nearly all clinical isolates have been found to produce both toxins in culture, or, more often from asymptomatic persons, neither toxin. These toxins are crucial to the pathogenesis and diagnosis of *C. difficile* diseases and are discussed more fully here. Certain strains of *C. difficile* do not produce either toxin and are considered to be nonpathogenic.

## EPIDEMIOLOGY

### Carriage

Fifty percent to 70% of normal infants are colonized with *C. difficile*, a process that likely occurs during birth or in the first few days of neonatal hospital exposure. The rates of *C. difficile* colonization dramatically decrease as the colonic mucosa matures over the first several months of life. Despite the high colonization rate, little or no clinical disease due to *C. difficile* occurs in young infants, a finding that has led to speculation that the mucosal adherence receptor for *C. difficile* is lacking in human infants.<sup>21,22</sup> Additional protective benefits may possibly be provided by maternal protective antibody or innate antibody synthesis.<sup>23</sup> The maturation of the colonic microflora, which may limit available nutrients, appears to play a role in reducing the bacterial burden of *C. difficile* in the first years of life.<sup>24</sup> Infants are generally believed to become susceptible to colitis from *C. difficile* at approximately 1 to 2 years of age. Adult levels of carriage are generally observed in children by the age of 3 years.<sup>21</sup> By adulthood, then, there are estimated to be 400 to 500 different species of bacteria that make up the colonic flora (90% of which are strict anaerobes), but *C. difficile* is not generally considered to be a normal constituent of the colonic bacterial flora of healthy adults.<sup>25</sup>

The asymptomatic carriage rate of *C. difficile* reported for healthy adult outpatients varies from 2% to 15% (average of approximately 3%).<sup>5,26</sup> In asymptomatic hospitalized patients,

however, the organism has been isolated with a prevalence of 10% to 25%, a finding that implicates nosocomial transmission as the primary form of acquisition for this organism.<sup>27</sup> McFarland and colleagues<sup>28</sup> studied 428 hospitalized patients and found that only 7% were culture positive for *C. difficile* on admission. An additional 21% of these patients acquired *C. difficile* during hospitalization, and 37% of this subset eventually developed a diarrheal illness.

*Clostridium difficile* can be isolated in 15% to 25% of patients with antibiotic-associated diarrhea and in 95% to 100% of patients with PMC.<sup>5</sup> In a prospective study, Gerding and associates<sup>29</sup> found that 30% of hospitalized adult patients with diarrhea had stools that were culture positive for *C. difficile* and determined that 87% of the cases of *C. difficile* colitis were nosocomially acquired. The results of several other studies indicate that as many as 1 in 100 hospitalized patients who receive antibiotics may develop *C. difficile* colitis, although the actual risk varies among institutions studied.<sup>30</sup>

### Transmission and Prevalence

Whereas most types of anaerobic infections are generally believed to arise from endogenous sources, *C. difficile* infection is usually acquired nosocomially.<sup>4</sup> Evidence for the method of transmission of the organism is found in institutional outbreaks, in animal models of disease, and in multiple epidemiologic studies of *C. difficile*-induced colitis.<sup>4,25,27,29</sup> The major disease-related reservoirs of *C. difficile* include human carriers and environmental surfaces. Clabots and colleagues<sup>31</sup> noted a direct correlation between the likelihood of *C. difficile* acquisition and the length of hospital admission. In another study, McFarland and coworkers<sup>28</sup> found that 21% of patients became newly colonized with *C. difficile* during their hospital stay, and that the organism was cultured at a higher frequency from patients who were exposed to *C. difficile*-positive roommates. These investigators also found that the organism was frequently isolated from hospital environmental surfaces. *Clostridium difficile* spores are generally resistant to commonly used disinfectants, a finding that may help explain the high isolation rate of the organism from nosocomial surfaces. In this same study, up to 59% of health care workers caring for *C. difficile*-positive patients were found to be culture positive as well. This result helps to explain the high rate of nosocomial transmission of the organism. Notably, the use of vinyl gloves by hospital workers markedly reduces transmission of *C. difficile*.<sup>32</sup>

### Risk Factors

*Clostridium difficile* colitis was initially described in association with clindamycin use. *Clostridium difficile* infections are still most frequently observed in patients receiving antibiotics, particularly in conjunction with hospitalization. Antimicrobials with activity against obligate anaerobic bacteria alter the normal microbial ecosystem and appear to put the patient at greatest risk of *C. difficile* infection.<sup>5,33</sup> In contrast, antimicrobials with little or no anaerobic activity appear to pose somewhat less of a risk. Classically, ampicillin, clindamycin, and cephalosporins are the agents believed to be most commonly associated with the development of *C. difficile* colitis<sup>34–36</sup> (Box 23-1). Clindamycin appears to have the highest relative risk. In one

\*Commonly associated.

†Rarely associated.

study, 10% to 20% of patients receiving this antibiotic developed diarrhea, and approximately 2% developed PMC.<sup>37</sup> The  $\beta$ -lactams, however, have probably been responsible for a greater number of cases of *C. difficile*-related disease, likely owing to the common use of this class of antibiotic.<sup>25,34</sup> The risk of *C. difficile* colitis appears to increase with the use of multiple antimicrobial agents, as well as with more prolonged courses of antibiotic treatment.<sup>29,38–40</sup> Brown and colleagues<sup>39</sup> found that greater than 10 days of antibiotic administration was a significant risk factor for the development of diarrhea due to *C. difficile*.

Although certain antibiotics carry a higher relative risk for the development of *C. difficile*-related disease, essentially all antibiotics have been reported to cause *C. difficile* colitis. Antimicrobials that are less commonly associated with *C. difficile* infections include the macrolides, chloramphenicol, the sulfonamides, the quinolones, tetracycline, and penicillins other than ampicillin and amoxicillin.<sup>41</sup> One report suggested that newer fluoroquinolones with broader antimicrobial activity, such as gatifloxacin, may be associated with increased incidence of *C. difficile* disease compared to those with more narrow spectrum.<sup>42</sup> Rare reports have described *C. difficile* with vancomycin, rifampin, and even metronidazole.<sup>25,39</sup> Therefore, disease due to *C. difficile* must be considered in any patient with diarrhea who has recently received any type of antibacterial agent. Notably, several case reports have also implicated antineoplastic drugs as occasional causes of *C. difficile* colitis (e.g., fluorouracil, methotrexate, cisplatin, doxorubicin, and cyclophosphamide).<sup>43</sup> These agents may act by altering the microecology of the gastrointestinal tract, either by intrinsic antimicrobial properties or by disruption of mucosal integrity.

Other, nonpharmacologic risk factors for the development of *C. difficile* infections have been reported in several studies and include advanced age, severe underlying illnesses, prolonged hospitalization, nasogastric intubation, fecal or urinary incontinence, intensive care unit stays, and recent surgery, especially involving the gastrointestinal tract.<sup>38–40</sup> In addition,

recent studies support the concept that immune responses may protect against infection.<sup>44</sup> In one study, the presence of an initial antibody response to toxin A was associated with protection against recurrence of *C. difficile* diarrhea.<sup>45</sup>

## DISEASE

*Clostridium difficile* infections represent a broad range of clinical disease, including asymptomatic carriage; mild, self-limited diarrhea; severe diarrhea; PMC; and toxic megacolon. A history of 5 to 10 days of antimicrobial exposure is typical. In some cases, however, there may be shorter incubation periods, and in others there may be delays of up to 10 weeks before the onset of symptoms is noted. Most commonly, patients present with mild diarrhea and lower abdominal cramping but with few systemic symptoms. In mild cases, symptoms may resolve simply with withdrawal of the offending antibiotic. Mucus may be present in the stools, but frankly bloody diarrhea occurs in only 5% to 10% of cases.<sup>14,25</sup> In patients with true colitis, fever, nausea, anorexia, dehydration, significant abdominal cramping or pain, and leukocytosis are usually present.<sup>5,26,46,47</sup> In certain cases, patients may have up to 20 loose stools per day. Patients with severe or fulminant colitis, however, may actually develop ileus, a complication that occurs most frequently in the elderly.<sup>26,27</sup>

Pseudomembranous plaques are present in up to 10% of cases of antimicrobial-induced colitis and usually indicate severe *C. difficile* disease.<sup>46,48</sup> In these cases, colonoscopy reveals the pathognomonic yellow-white plaques adherent to an erythematous mucosa. The lesions are generally found in the rectosigmoid and descending colon but, occasionally, can also be present throughout the intestinal tract. The plaques range in size from 2 to 10 mm and are composed of fibrin, mucus, necrotic epithelial cells, and leukocytes. In certain cases, the lesions can coalesce to form extensive areas of involvement. PMC due to *C. difficile* can lead to significant protein loss and result in hypoalbuminemia.<sup>49</sup>

Paralytic ileus, colonic dilation, and toxic megacolon represent a spectrum of rare but serious complications of PMC. With these complications, diarrhea often subsides and the patient may eventually develop abdominal distention and extreme pain. Also, the physical examination reveals features of an acute abdomen. In these situations, the risk of intestinal perforation is significant and precludes sigmoidoscopy. Surgery, when required, is difficult and is generally associated with a marked increase in mortality.<sup>49</sup>

## PATHOGENESIS

Unlike many bacterial causes of inflammatory colitis, *C. difficile* is noninvasive. The pathogenesis of *C. difficile*-induced colitis is a result of one or both of two heat-labile exotoxins (toxin A and toxin B) produced by the organism in the setting of an altered colonic flora.<sup>24,50,51</sup> Approximately 25% of colonizing strains do not produce toxins and are not pathogenic. In general, toxigenic strains produce both toxins A and B. The relative amounts of each toxin produced by any one strain are variable and do not necessarily correlate with severity of disease. Toxin A is a 308-kDa enterotoxin and cytotoxin that leads to disruption of intestinal intercellular junctions, hemorrhagic fluid secretion, mucosal damage, and inflammation

in animal models.<sup>24</sup> Toxin A likely binds to mucosal cells via a glycoprotein receptor on human intestinal epithelial cell surfaces, and the cellular uptake of toxin A has several characteristics of a receptor-mediated endocytic process.<sup>52</sup> The major intracellular target of toxin is the monoglucosylation of the Rho family of small G proteins. Rho proteins regulate a variety of cellular functions, most notably actin microfilament organization.<sup>53,54</sup> In addition, toxin A may exert some of its effects via a Rho-independent pathway, signals likely triggered directly by cell binding.<sup>55</sup> A key factor in the pathophysiology of PMC is the generation of an intense inflammatory response, a reaction that is likely elicited by toxin A-induced cytokine release (interleukins-1, -6, and -8 and tumor necrosis factor) from chemotactic neutrophils, monocytes, mast cells, and epithelial cells found in the tissues of the intestinal mucosa.<sup>51,56,57</sup>

Toxin B is an approximately 270-kDa protein that exerts cytotoxic effects toward certain tissue culture cell lines that can be up to 1000 times greater than that observed for toxin A.<sup>51,52</sup> Toxin B, however, does not exert enterotoxic activity in most animal models. Although it is clear that toxin A is critical to the development of clinical disease, roles for toxin B are less clear.<sup>24</sup> Intriguingly, toxin B also appears to inactivate the Rho proteins in certain cell types. Thus, differences in the biologic actions of toxins A and B must be related to differences in cell binding, mechanisms of cellular uptake, Rho-independent effects of the toxins, or a combination of these. Toxin A-negative, toxin B-positive strains of *C. difficile* have been shown to clearly induce serious disease.<sup>58,59</sup>

## DIAGNOSIS

The diagnosis of *C. difficile* infection relies heavily on clinical acumen as well as appropriate laboratory evaluation.<sup>20</sup> A patient producing three or more unformed stools per day for at least 2 days in the setting of exposure to antimicrobial or antineoplastic agents can be considered to have the syndrome of antibiotic-associated diarrhea.<sup>60,61</sup> Endoscopy can be used to visualize pseudomembranes, which, if present, are highly suggestive of *C. difficile*-induced colitis.<sup>4,29</sup> This technique, however, is expensive, not always readily available, and runs the risk of serious complications, including colonic perforation. Therefore, endoscopy is not generally recommended except for the unusual and critically ill patient who would benefit from an immediate diagnosis of PMC so as to avoid exploratory laparotomy. In the vast majority of cases, laboratory evaluation is the preferred diagnostic approach, and several techniques are currently in use.

The cytotoxin (or tissue culture) assay detects primarily toxin B in stool filtrates by observing the characteristic cytotoxic changes that this toxin produces in standardized tissue culture cell lines. Because the vast majority of toxigenic *C. difficile* strains produce both toxins A and B, this assay is considered diagnostic of toxigenic *C. difficile*-induced colitis. The assay is time-consuming and requires trained technologists to examine the cell lines for cytotoxic effect. The diagnosis can be confirmed by neutralization of the cytotoxic effect using antitoxin specific for *C. difficile*. The sensitivity of the cytotoxic assay ranges from 70% to 100%, with a specificity of 95% to 99%.<sup>20,60,62</sup>

A correctly performed stool culture is extremely sensitive in detecting the presence of *C. difficile*. The specificity of culture

is low, however, because culture techniques do not distinguish between nontoxigenic (and therefore nonpathogenic) and toxigenic strains of the organism. In addition, culture requires several days to achieve isolation and identification of the organism.<sup>20,60</sup>

The enzyme immunoassay (EIA) detects the presence of toxins A or B in stool filtrates and is a faster technique for diagnosing *C. difficile* infection. The specificity of this technique approaches that of the cytotoxin assay (75% to 100%), but the sensitivity of various commercial kits varies from 63% to 94%. Because of this wide variation in sensitivity, the performance history of any particular kit must be known to ascertain its clinical usefulness for any specific patient.<sup>20,63</sup> These assays are widely used and can be performed on two or three specimens to increase diagnostic yield.<sup>64</sup>

The latex agglutination (LA) test, although initially thought to detect the presence of toxins A or B, in fact detects the unrelated but *C. difficile*-specific enzyme, glutamate dehydrogenase.<sup>65</sup> LA tests are relatively insensitive compared to other assays (48% to 68%).<sup>20,60</sup> Furthermore, this antigen-based test, like stool culture, cannot distinguish nontoxigenic from toxigenic strains.

Fecal lactoferrin testing by latex agglutination provides a sensitive measure of inflammatory enteritis and correlates well with EIA and cytotoxin assays in patients with *C. difficile* infections.<sup>66,67</sup> As with a fecal leukocyte test, a positive fecal lactoferrin test in a patient with antibiotic-associated diarrhea should alert the clinician to the possibility of *C. difficile* colitis but is not diagnostic of the syndrome and should be followed by one of the specific tests listed previously.

Polymerase chain reaction (PCR) can detect toxigenic *C. difficile* by amplification of the toxin A or B gene or both genes. This research-based assay is under development and appears to be extremely sensitive.<sup>68,69</sup> If specificity issues and turnaround time can be improved, the test may prove valuable in the future.

## TREATMENT AND PROGNOSIS

### Initial Therapy

In patients with mild *C. difficile*-associated diarrhea, cessation of the offending antimicrobial, if possible, may be all that is required. Specific therapy is indicated for patients with more severe or persistent symptoms and also for those patients who require continuation of their original antimicrobial agents (Table 23-1). Initial therapy with oral metronidazole 250 mg four times daily, or oral vancomycin 125-mg capsules four times daily or a 500-mg intravenous preparation given orally, appears to be equally efficacious, with cure rates greater than 95% when administered for 10 days.<sup>5,70,71</sup> Some symptomatic improvement is usually seen within 24 to 72 hours of initiating therapy, although diarrhea and colitis may persist for several additional days. Metronidazole has generally been proposed as the therapy of choice because this agent is inexpensive and may reduce an important potential problem of vancomycin—selection for the emergence of other vancomycin-resistant organisms.<sup>5</sup> Vancomycin is preferred during pregnancy or lactation and is employed when patients fail to respond to metronidazole within the first 3 to 5 days.

**Table 23-1 Treatment of *Clostridium difficile*-Associated Disease**

Antibiotic	Cure Rate (%)	Relapse Rate (%)	References
Metronidazole* 250 mg PO qid × 10 days	>95	~5	5, 25, 71
Vancomycin 125 mg PO qid × 10 days	>95	~15	5, 71, 72, 75
Teicoplanin 100 mg bid × 10 days	>95	~8	72
Bacitracin 25,000 units PO qid × 10 days	~80	~30	74, 75

bid, twice a day; PO, by mouth; qid, four times a day.

\*Relapses should be re-treated with the initial regimen because greater than 90% will achieve cures; relapse rates were not significantly different from those of vancomycin in trials using both antimicrobial therapies.

The relapse rates for metronidazole and vancomycin are similar (4% to 20%). The experience with oral teicoplanin 100 mg twice daily for 10 days is very limited, but in initial reports, this agent appears to have a similar response rate to that of oral vancomycin.<sup>72</sup> Agents such as bacitracin and cholestyramine have inferior cure or relapse profiles and should not be used as initial therapy.<sup>73-75</sup>

Although oral metronidazole is well absorbed from the upper gastrointestinal tract, bactericidal concentrations of the drug in feces can be measured in patients with inflammatory diarrhea.<sup>76</sup> Major side effects of metronidazole include nausea, the development of a metallic taste, and a disulfiram-like reaction that occurs with ingestion of alcohol. Oral vancomycin is not appreciably absorbed and is excreted unchanged in the stool. For patients who cannot take oral therapy or in whom oral therapy may be unreliable (notably patients with abdominal surgery, or those with ileus or toxic megacolon), intravenous metronidazole appears to be effective and bacteriocidal fecal concentrations can be achieved.<sup>76,77</sup> If ileus is present, oral metronidazole or oral vancomycin (500 mg four times daily) can be instilled via nasogastric tubes with documented efficacy.<sup>5,70,78</sup> Intravenous vancomycin, in contrast, does not undergo appreciable gastrointestinal excretion and should not be used for the treatment of *C. difficile*-associated disease.

### Relapses

Up to 20% of patients treated for *C. difficile*-associated disease will have relapse after cessation of therapy. These relapses usually occur within 2 weeks after initial therapy is discontinued. Relapse is probably due to the persistence of antibiotic-resistant *C. difficile* spores rather than the development of antibiotic resistance of the vegetative organism. In patients with relapse, re-treatment with the initial agent will result in a greater than 90% cure rate.<sup>5,70</sup> Multiple empirical regimens have been evaluated in patients who suffer two or more recurrences. Most of these regimens focus on efforts to repopulate the normal colonic flora. Perhaps most encouraging is the use of *Saccharomyces boulardii* in combination with standard antimicrobial therapy in patients with recurrent infection. A blinded, controlled study demonstrated a reduced rate of

relapse with this particular combination therapy when compared with standard antimicrobial therapy alone.<sup>79</sup> There are anecdotal reports of successful therapy using metronidazole followed by oral *Lactobacillus*,<sup>80</sup> vancomycin in combination with rifampin or cholestyramine,<sup>81–83</sup> tapering or pulse doses of vancomycin,<sup>84</sup> rectal instillation of stool or mixed broth cultures,<sup>85</sup> and intravenous immune globulin.<sup>86,87</sup> None of these therapies appear to be uniformly effective, and their use is empirical for any particular patient. With increasingly worrisome antibiotic-resistant enteric organisms (e.g., vancomycin-resistant enterococci), clearly the need is increasing for chemotherapeutic or immunologic agents (other than antimicrobials) that block the dramatic effects of the toxin(s),<sup>88</sup> such as antitoxic antibody, pharmacologic blockers such as phospholipase A<sub>2</sub> or cyclooxygenase inhibitors, or platelet-activating factor antagonists.<sup>89</sup>

## PREVENTION AND CONTROL

*Clostridium difficile*-associated disease is in general acquired nosocomially in the context of concurrent antimicrobial therapy. Prevention and control efforts, therefore, are targeted at interrupting the horizontal transmission of the organism and restricting the use of antimicrobials. Although no specific barrier methods have been completely effective, it appears likely that the use of gloves, hand washing, and the enteric isolation of symptomatic infected patients reduce transmission of the organism.<sup>28,32,39,90–92</sup> It is less clear whether isolation of asymptomatic carriers is helpful.<sup>31</sup>

Environmental surfaces in rooms of patients with *C. difficile*-associated disease have a high rate of *C. difficile* contamination, with resistant spores presenting a challenge in terms of disinfection.<sup>28</sup> Disinfection of the contaminated hospital environment with hypochlorite, formaldehyde, or glutaraldehyde solutions reduces the amount of *C. difficile* cultured from these surfaces. Therefore, although no well-controlled trials of environmental disinfection have been published, this may be an important adjunctive measure to reduce nosocomial transmission of the organism.<sup>92,93</sup>

Given that there is a strong association of *C. difficile* colitis with antibiotic use, restricting the use of the more common offending agents would likely be helpful in controlling the incidence of *C. difficile*-related disease. Restriction of clindamycin use has been reported to reduce the incidence of *C. difficile*-associated diarrhea, but few additional studies have addressed this issue.<sup>39,94,95</sup> Furthermore, the majority of studies that have examined prophylactic measures in the setting of outbreaks instituted multiple control measures simultaneously, thus making it difficult to distinguish the relative merits of any individual intervention.

Prophylactic therapy for patients already receiving antimicrobials is not well studied. One trial using *S. boulardii* during antimicrobial administration and for 2 weeks thereafter did demonstrate a reduction of antibiotic-associated diarrhea.<sup>79</sup> In this study, the incidence of *C. difficile*-associated diarrhea was reduced when compared with placebo but did not reach statistical significance. Other agents reported to be useful for prophylaxis include bovine *C. difficile* antibodies and *Lactobacillus* in the form of yogurt or acidophilus milk.<sup>80,96</sup> Initial results appear promising, but further clinical testing is required to determine the true utility of these regimens.

## OTHER ENTERIC *CLOSTRIDIUM* INFECTIONS

### *Clostridium perfringens*

*Clostridium perfringens* type C has been the cause of both sporadic and epidemic cases of necrotizing enteritis. Clinical entities such as *Darmbrand* ("bowel gangrene") in postwar Germany during the 1940s and pigbel<sup>97</sup> in the Papua New Guinea highlands have been attributed to this organism, which elicits alpha and beta toxins capable of causing the enteritis. Poor nutrition and episodic dietary indulgence have been associated with these entities, with investigators suggesting that a low level of digestive enzymes in people with low protein dietary intake may prevent normal inactivation of bacterial toxins.<sup>98</sup> Clinically, previously healthy patients present with a necrotizing enteritis syndrome that may include anorexia, nausea, vomiting, abdominal pain, and hematochezia and may progress to sepsis. Complications are common and include peritonitis secondary to bowel perforation, ileus, and chronic scarring leading to malabsorption, obstruction, or fistulas.

Multiple lines of evidence in animal and human models suggest that it is the beta toxin of *C. perfringens* type C that is responsible for clinical disease.<sup>98–100</sup> Serum beta antitoxin titers were significantly increased after illness with pigbel in 12 of 21 cases in Papua New Guinea, and administration of type C antiserum resulted in a 30% decrease in the need for surgery, reducing mortality from 43% to 19%.<sup>97,101</sup> Finally, active immunization against the beta toxin has proved to be effective in preventing pigbel.<sup>99,100</sup>

Therapy for these enteritides includes bowel decompression, supportive care, and surgical resection of involved bowel in patients who have perforation, sepsis, or a palpable mass lesion. Antiserum to *C. perfringens* type C containing beta antitoxin can be administered. The active beta toxin vaccine can be used prophylactically in areas where disease is likely to occur.

### *Clostridium botulinum*

*Clostridium botulinum* is the cause of botulism and is due to intoxication with a group of similar clostridial neurotoxins (types A to G) that predominantly affect the peripheral neuromuscular junction and autonomic synapses.<sup>102</sup> Although classically associated with food-borne, wound, and infantile presentations, an inhalational form in the setting of bioterrorism has been discussed.<sup>102</sup> All forms lead to similar neurologic presentations.

Food-borne botulism is most frequently recognized during outbreaks and appears to be due to ingestion of toxins found in home-canned vegetables, fruits, and fish products.<sup>103</sup> The toxin is absorbed in the duodenum and jejunum, passes into the bloodstream, and acts at peripheral cholinergic synapses much like tetanus toxin to proteolytically cleave synaptobrevin II to prevent the vesicular docking and extracellular release of acetylcholine; this induces paralysis in the motor system and autonomic dysfunction in autonomic ganglia and parasympathetic nerve terminals.<sup>102,104</sup>

Food-borne botulism develops 24 to 36 hours after ingestion of the toxin and may initially cause diarrhea, dry mouth, and nausea.<sup>102</sup> Evidence of cranial nerve dysfunction soon follows—notably blurred vision, diplopia, dysphagia, and dysarthria—eventually spreading to the upper and lower

extremities and the respiratory musculature.<sup>104,105</sup> Autonomic dysfunction may lead to constipation, alterations in heart rate and blood pressure, and urinary retention.<sup>106</sup> Treatment of botulism is primarily supportive, with particular attention given to ventilatory support.<sup>102,104</sup> Antitoxin therapy with equine serum is available, although no controlled trials have been performed. Purgatives may be given initially for contaminated food still present in the gastrointestinal tract, but they should be avoided in the presence of ileus.

*Clostridium tetani* is reviewed in Chapter 43. Other clostridial infections causing myonecrosis or gangrene (often in combination with other anaerobes or staphylococci or streptococci) are beyond the scope of this chapter and are reviewed in standard textbooks of infectious diseases.<sup>97</sup>

## SUMMARY

*Clostridium difficile* infection is a common cause of nosocomial diarrhea that generally occurs in the setting of antimicrobial exposure. Infections require the presence of both the *C. difficile* organism and its unique enterotoxin, toxin A. *Clostridium difficile* infections comprise a spectrum of disease ranging from mild diarrhea to toxic megacolon and death. Treatment with oral metronidazole or vancomycin is effective, and prevention of nosocomial horizontal transmission by barrier techniques, antimicrobial restriction, and enteric isolation may deter future outbreaks.

# Helicobacter pylori Infections

BARRY J. MARSHALL  
ROBERT H. GILMAN

## INTRODUCTION

*Helicobacter pylori* colonizes the mucus layer of the human stomach and causes inflammation termed *active chronic gastritis*.<sup>1</sup> *H. pylori* can easily be identified using simple techniques available in all microbiology laboratories. The bacterium infects more than half of the population of the world, is more common in tropical countries, and in some people it causes peptic ulceration or gastric cancer. In the tropics it may be associated with reduced gastric acid,<sup>2</sup> increased diarrhea, and malnutrition.<sup>3</sup> *H. pylori* can be diagnosed by direct examination of gastric mucosal biopsy tissue obtained at endoscopy, or noninvasively using serology, a urea breath test, or a fecal antigen test. Cure of the infection is possible in most patients with a two-week treatment using combinations of antimicrobial agents and acid-lowering drugs.<sup>4</sup> In the tropics, due to poor sanitation, reinfection is common.<sup>5-7</sup> For this reason there is currently much interest in the development of an oral vaccine to prevent new infections.

## AGENT

*H. pylori* is the type strain of a new genus of spiral-shaped bacteria named *Helicobacter*. Their morphology and sheathed flagella may facilitate motility in the mucus layer of the gastrointestinal tract. *H. pylori* is microaerophilic, which means that it prefers a reduced amount of oxygen for growth, but is not anaerobic. This is probably the environment found in the mucus layer of the gut, a transitional zone between the anaerobic lumen and the oxygenated mucosa. The characteristics and growth requirements of *H. pylori* are listed next.

Morphologically, *H. pylori* is a gram-negative spiral, 3.5  $\mu\text{m}$  long  $\times$  0.6  $\mu\text{m}$  thick, with 1.5 wavelengths and four to seven sheathed flagella at one end of the organism, as shown in Figure 24-1. In tissues *H. pylori* appears spiral and lies close to the gastric epithelial cells and in the mucus glands. Squashed or smeared fresh gastric biopsy specimens may be stained by Gram stain or examined by phase contrast microscopy.<sup>8,9</sup> In histologic sections *H. pylori* stains well with Giemsa, toluidine blue, or silver stains. Hematoxylin and eosin (H&E) stain does not adequately demonstrate *H. pylori*.

In culture, *H. pylori* appears longer and spiral forms are not as obvious. Usually comma shapes and U-shapes (unseparated dividing organisms) are seen.<sup>10</sup>

## Culture

*H. pylori* is microaerophilic, growing in reduced  $\text{O}_2$  at 37°C in 4 to 6 days on fresh (preferably) chocolate or blood agar. The “*Campylobacter* atmosphere” generated by a commercial *Campylobacter* kit in a gas jar provides atmosphere for *H. pylori* culture. If available, a 10%  $\text{CO}_2$  incubator also provides excellent growth conditions. “*Campylobacter*” atmospheres are also available as premixed cylinders that can be used to fill a sealable plastic bag with a moist paper towel inside. If nothing else is available, a candle jar with moist paper towels in the bottom will provide an adequate atmosphere, and even gas-generating methods such as the “steel wool and Alka Seltzer” idea of Pennie and colleagues<sup>11</sup> can be used.

## Selective Media

Although *H. pylori* can be isolated easily from gastric biopsy samples onto nonselective media, 20% of patients have bacterial contamination of the biopsy, and overgrowth of commensal flora will make isolation of *H. pylori* difficult. To maximize the isolation rate, a selective medium can be made by adding vancomycin, trimethoprim, and amphotericin to the culture medium.<sup>12</sup> Ready-made selective media for *H. pylori* culture are available,<sup>13</sup> or *Campylobacter* isolation media such as Skirrow’s medium may also be used.<sup>14</sup>

## Identification

On blood or chocolate agar, transparent or pale-yellow 1- to 2-mm “water spray” colonies appear after 3 to 6 days. They are strongly positive for catalase, oxidase, and rapid urease. In the last-named test, a pink color is observed within 5 minutes of applying a colony to Christensen’s urea agar. The organism may also be grown in broth such as shaking tubes of *Brucella* broth<sup>15</sup> or in gas-permeable shaking bags<sup>16</sup> in a  $\text{CO}_2$  incubator, or in fermenters.<sup>17</sup>

**FIGURE 24-1** *Helicobacter pylori* (3.5  $\times$  0.6  $\mu\text{m}$ ) has a smooth wall and four to seven sheathed flagella arising from only one end of the cell. These features distinguish it from *Campylobacter* spp., which have rough cell walls and a single, thinner, unsheathed flagellum at each end of the cell. Other *Helicobacter* spp. have distinguishing features such as many flagella and axial filaments (*H. felis* from cats) or flagella sprouting from the sides of the organism (*H. mustelae* from ferrets). Mature organisms appear as spiral forms with 1.5 wavelengths.

## Pitfalls

When subculturing *H. pylori*, one should always examine the Gram's stain morphology of *H. pylori* as well as perform the biochemical identification tests described earlier. Contaminating organisms may appear similar to the naked eye and are often urease, oxidase, or catalase positive.

## EPIDEMIOLOGY AND TRANSMISSION

*H. pylori* infects more than 70% of persons in most developing countries and about 30% of persons in developed countries. In societies that have recently emerged to affluence (such as Japan), *H. pylori* is still quite common and infects most persons over the age of 40 years.

*H. pylori* is acquired in childhood, probably by the fecal-oral route. The bacterium has been isolated from the feces of children in The Gambia<sup>18</sup> and polymerase chain reaction (PCR) techniques have demonstrated the genome of the organism in water from Peru.<sup>5</sup> In developing countries, children may be infected at the rate of 15% per annum so that most of the population is infected by adulthood. The initial infection with *H. pylori* may be somewhat precarious in that some children lose the infection spontaneously for a time but then reacquire it from the environment. This may occur several times before the child maintains a stable permanent gastric infection.<sup>19</sup> Initially the infection may spread from one parent to one of the children in the family, then spread to other family members, siblings, or the uninfected parent by fecal contamination, and even aerosols of vomitus.<sup>20,21</sup> Thus the infection is transmitted from one generation to the next, but young children appear to amplify the infection rate.<sup>22</sup>

The exact mechanism of spread is still somewhat controversial. *H. pylori* DNA is sometimes present in the dental plaque of some infected persons,<sup>23</sup> but actual live organisms are only very rarely culturable from the oral cavity. Thus the organisms might occasionally be carried to the mouth in gastric reflux, but probably do not live in the mouth. Oral-oral spread of *H. pylori* seems possible but has been hard to demonstrate. For example, in Belgium, investigators studied infants born to 67 infected mothers but could detect only one new *H. pylori* infection by breath test during a 12-month

period.<sup>24</sup> This may mean that most new infections in developing countries are fecal-oral, that is, from other children, relatives, or from environmental sources. The prevalence rate in developing countries, as compared with Western countries, is shown in Figure 24-2.

## PATHOGENESIS

### Acute Infection

Immediately after ingestion by a healthy person, it is thought that the urease enzyme of *H. pylori* enables the bacterium to survive in acid by generating ammonia and bicarbonate from urea present in the gastric juice.<sup>25</sup> Vague symptoms of epigastric discomfort then commence 72 hours after ingestion of the organism. Gastric acid secretion may initially increase, associated with varying degrees of epigastric discomfort<sup>26</sup> followed by vomiting episodes.<sup>20,27</sup> Symptoms usually settle after several days as the bacterium induces achlorhydria. The cause of the achlorhydria is unknown; however, it might involve the action of a bacterial toxin,<sup>28</sup> ammonia, or the presence of cytokines, especially interleukin-1 $\beta$ .<sup>29</sup>

In the tropics, achlorhydria has long been associated with malnutrition and susceptibility to enteric infections such as *V. cholerae* and enterotoxigenic *E. coli* infections.<sup>30,31</sup> So far, *H. pylori* infection is the only known environmental agent proven to cause achlorhydria. Since the acute infection is associated with long periods when the gastric acid barrier is impaired, *H. pylori* may increase susceptibility to the other enteric pathogens and thus be an important pathogen in the pediatric age group.<sup>32</sup> Perhaps related to the achlorhydria, acute *H. pylori* infection is associated with a mild growth arrest,<sup>33</sup> and in a few studies infected children grow up shorter than controls.<sup>34,35</sup>

The achlorhydria of acute *H. pylori* is "chemically induced" and is reversible, unlike that seen after many years of the chronic *H. pylori* infection, where atrophy of gastric mucosa causes acid secretion to be irreversibly diminished (see following discussion).<sup>32</sup>

### Attachment

*H. pylori* has several attachment mechanisms that enable it to selectively colonize gastric mucosa but not intestinal mucosa. To various degrees, *H. pylori* is adherent to Lewis B antigen,<sup>36</sup> phosphatidylethanolamine,<sup>37</sup> and ganglioside GM<sub>3</sub>,<sup>38</sup> all of which are present on the gastric mucus epithelial cells. In addition, *H. pylori* synthesizes Lewis X antigen which may be a mechanism of "molecular mimicry" to make the organism similar to the host tissue, thus attenuating the immune response.<sup>39</sup> Once attached, *H. pylori* induces the production of interleukin-8 (IL-8) which in turn attracts neutrophils.<sup>40</sup> If deep colonization occurs in the acid secreting mucosa, secretion of IL-1 by inflammatory cells may inhibit acid secretion

### Cytotoxins

The effect of *H. pylori* on the gastric mucosa is more severe when the bacterium produces cytotoxins. The most notable of these is CagA, which is one component of about 30 genes in the cagA pathogenicity island. This structure, present in most

**FIGURE 24-2** The prevalence of *Helicobacter pylori* in developing and Western countries. In developed countries, *H. pylori* is decreasing in prevalence so that most of the infections are in those over the age of 50 years who likely acquired the infection during childhood. The infection in young persons is only seen in immigrants from high-risk countries.

**FIGURE 24-3** Relationships of cytotoxin genes and proteins. The left side diagrams a representative immunoblot pattern of a patient with a duodenal ulcer and *Helicobacter pylori* infection. The 127-kDa band is the cytotoxin-associated gene A (*cagA*) product. The *cagA* pathogenicity island has a higher guanine + cytosine content than the rest of the *H. pylori* genome. This suggests that the *cagA* gene group has long ago been imported from a different genus. The *vacA* (vacuolating toxin A) gene has two main subunits (*s* and *m*), and these can each be in two subtypes (*s1*, *s2*, and *m1*, *m2*). When *s2* is present, the cytotoxic potential of the organism is very weak and is not usually associated with peptic ulcer, and the *CagA* island is usually absent.

strains, codes for a “Type IV” secretion system. This causes a hollow pilus-like structure to form which then injects the CagA toxin protein into the epithelial cell. CagA toxin emulates at least two growth-factors causing the epithelial cell to adopt a less structured, more mobile, primitive form. Thus the integrity of the gastroduodenal epithelium is compromised and nutrients are able to leak up from between the cells and towards the *H. pylori*. In developed countries, CagA is present in only 60% of strains, whereas in most tropical or developing countries (Peru is a good example) more than 90% of strains are CagA-positive.

Linked to the *cagA* island is a propensity for such isolates to produce VacA toxin of a more virulent subtype. VacA is a membrane pore which leads to leaky intracellular organelles and the appearance of “vacuoles” in the cells. The two *vacA* subunits “*s*” and “*m*” can each exist in two forms, *s1* or *s2*, and *m1* or *m2*; only *s1* (*m1* or *m2*) are associated with active cytotoxin (Fig. 24-3).<sup>41</sup> Other toxins are BabA (Blood-Group Antigen Binding Toxin A)<sup>42</sup> and iceA (Induced with Contact to Epithelium). Toxin-producing strains (*cagA*, *vacA*, BabA) are more likely to be present in persons with duodenal ulcer or with gastric cancer because they upregulate the degree of mucosal inflammation. This effect is also modulated by various interleukin polymorphisms in the patient, such as IL-1 $\beta$  and its receptor so that some individuals with a virulent strain could experience a 5–50 fold increased risk of cancer from a *H. pylori* infection.<sup>43,44</sup>

## DISEASE ASSOCIATIONS AND CLINICAL MANIFESTATIONS

### Active Chronic Gastritis

Chronic gastritis refers to the histological presence of mononuclear cells (lymphocytes and plasma cells) in the gastric mucosa. Histologic chronic gastritis is associated very closely with *H. pylori* and there are few patients with this finding who do not have the organism.<sup>45</sup> There is also a variable amount of neutrophilic infiltration of the mucosa, typically invading the necks of mucous glands. This latter appearance

gives the name “active” or “acute” to the typical histologic appearance of “active chronic gastritis.”<sup>46</sup> Because the cause of chronic gastritis was unknown before the discovery of *H. pylori*, the terminology was confusing and nonstandardized. In most of the literature, terms such as “atrophic gastritis,” “superficial gastritis,” “simple gastritis,” “antral gastritis,” and “type 1 gastritis” all refer to the histology of *H. pylori* infection. The various classifying and descriptive terms for the lesion have been well described in several papers.<sup>47–49</sup>

In the antrum of the stomach, *H. pylori* is most numerous on the surface of the epithelium (beneath the mucus layer) but it also lives in the mucus-secreting glands. In the body of the stomach (corpus), almost all of the organisms are found on the surface. The inflammation tends to collect near the bacteria. Thus in the corpus, the appearance is that of a “superficial gastritis,” whereas in the antrum, the inflammation is deeper. In either place the lesion can be associated with lymphoid follicles.<sup>50</sup>

In the long-standing case of chronic active superficial gastritis, the superficial inflammation includes a predominance of PMNs. In contrast, in the deep portion of the glands below the necks the inflammation is predominantly chronic with lymphocytes surrounding destroyed remnants of gastric deep glands; an appearance that has been called the glandular lymphocytic adherence lesion. As this deep inflammation becomes more extensive, the deep glands become islands separated by chronic inflammation, they are less tightly packed, and their depth decreases. This decrease is called chronic atrophic gastritis. Another way deep glands are replaced is through intestinal metaplasia. The degree of deep glands lost through either inflammation or intestinal metaplasia determines how extensive is the chronic atrophic gastritis.<sup>51</sup> Chronic atrophic gastritis is a precancerous lesion probably due to the effects of long-term hypochlorhydria and the resultant presence of abnormal gastric flora. In general, inflammation, both superficial and deep, is more severe in the antrum, less in the corpus, and least in the cardia.<sup>52</sup> In both the antrum and the corpus, the preceding lesions may be associated with lymphoid follicles. Lymphoid follicles are rarely seen in the gastric mucosa except after *H. pylori* infection.<sup>53</sup>

Attachment of the bacterium causes damage to the cytoskeleton of the epithelial cells so that they bulge out rather than maintain a flat luminal surface. Under periodic acid–Schiff staining, the apical mucus content of infected gastric mucosa is less than normal and cells are shorter. These changes have been termed the destructive mucin lesion of the covering gastric epithelium.<sup>49,54</sup>

Over the lifetime of the infected person, inflammation may destroy the glandular elements (atrophy) and intestinal cells often replace gastric mucus-secreting epithelium (intestinal metaplasia). The resulting atrophic gastritis is the final “burned out” phase of *H. pylori* infection, usually seen in older persons. In tropical countries, however, where *H. pylori* may have been present from a very early age, atrophic gastritis may be seen in young adults and is believed to be a major risk factor for gastric cancer.<sup>55</sup>

### Duodenal and Gastric Ulcer

The most obvious disease associated with *H. pylori* is peptic ulceration (Fig. 24-4). More than 90% of duodenal ulcers are associated with toxin-producing *H. pylori*.<sup>56</sup> When a patient with a duodenal ulcer does not have *H. pylori* infection, etiologic factors such as Zollinger-Ellison syndrome or nonsteroidal anti-inflammatory drug (NSAID) use are likely.<sup>57</sup>

In gastric ulcer, two causes prevail, and many patients will exhibit both. Most gastric ulcers have *H. pylori* and these can be identified by presence of the bacterium or chronic gastritis. The stomach is also directly exposed to ingested agents such

as an NSAID and is more likely than the duodenum to ulcerate in response to these agents. Therefore, in the United States, about 50% of gastric ulcers are not associated with histologic chronic gastritis or *H. pylori* but are caused by NSAIDs.<sup>48</sup>

In tropical countries where NSAIDs are less widely used and *H. pylori* is very common, most gastric ulcers are caused by *H. pylori*.<sup>58</sup> Perhaps because of this, gastric ulcers are more likely to be malignant and require endoscopy and biopsy for histologic examination.

The proposed causation of duodenal ulcer is as follows. Persons with *H. pylori*, but with colonization mainly in the antrum, have high acid secretion but a defective mucosal barrier. Inflammation in the antrum impairs the growth of D cells (which make somatostatin) and thus decreases their inhibitory effects on the gastrin-producing G cells. This results in higher gastrin production, which may in turn, over the lifetime of the patient, cause a hyperplasia of the acid-secreting mucosa. Gastric mucus cells normally present in the duodenal bulb become colonized with *H. pylori*, seeded from the infection present in the antrum. Neutrophil invasion of the duodenal epithelium (duodenitis) increases susceptibility to ulceration. Inflammation is more severe when the *H. pylori* secretes CagA, thus associating the cytotoxin with duodenal ulcer.<sup>59,60</sup>

All persons with peptic ulcer should be tested for *H. pylori* and treated with antimicrobial agents when evidence of the infection exists.<sup>4,61</sup> Ulcer recurrence is less than 10% when *H. pylori* is eradicated, whereas more than 90% of ulcers recur when the bacterium persists.<sup>62</sup> Thus, most patients are cured of their ulcer disease with effective antibiotic treatment.<sup>63</sup>

**FIGURE 24-4** Disease associations with *Helicobacter pylori* (HP). The large circle represents a typical population in a developed country where 60% of persons are not infected with *H. pylori*. The darker circle represents the 40% of persons who are infected with *H. pylori*. Even so, nearly all the duodenal ulcers and gastric ulcers occur in the *H. pylori*-positive group. Each year, 1% of infected patients undergo transition from asymptomatic gastritis to symptomatic peptic ulcer. Note that most gastric adenocarcinomas and gastric mucosa-associated lymphoid tissue (B-cell) lymphomas also occur in the *H. pylori*-positive persons. Controversy reigns as to the role of *H. pylori* in persons with dyspepsia but in whom ulcers are not found: Should *H. pylori* be treated in these persons, or ignored?

### Gastric Cancer

#### Adenocarcinoma

Worldwide, gastric cancer is the second most common cancer, the high prevalence areas being Brazil, Colombia, Korea, China, and Japan. *H. pylori* infection affects more than half the population in these countries.<sup>63</sup> The incidence of gastric cancer has declined in the United States since 1930. It was the most common cancer, but now it ranks about ninth.<sup>64</sup>

*H. pylori* confers an approximately sixfold risk of gastric cancer, accounting for about half of all gastric cancers.<sup>63</sup> Thus, in most tropical countries where *H. pylori* is prevalent, gastric cancer is also common. In India, Bangladesh, the Middle East, southern China, and some African countries, however, *H. pylori* is prevalent but gastric cancer is not. This paradox suggests that genetic, dietary, and other unknown environmental factors are also important in the etiology of adenocarcinoma.<sup>64,65</sup>

The proposed chain of events in gastric carcinoma starts with a very early (age 1 to 5 years) infection with *H. pylori* so that the corpus mucosa is damaged during childhood. In this setting, ulcers are unlikely but a large area of the stomach is involved in the process. Damaged areas coalesce into chronic atrophic gastritis and acid secretion diminishes, eventually allowing other organisms to colonize the stomach.<sup>66–68</sup> In this setting, nitrates can be changed to nitrites and then to nitrosamines, which are carcinogenic. In the presence of ammonia, inflammation itself can cause nitrosamines to form in the mucosa. Inflammation is more severe when the *H. pylori* secretes toxin, thus associating several cytotoxins with gastric cancer.

# The Ulcer-Cancer Controversy

It has been well demonstrated that CagA toxin–positive strains of *H. pylori* are associated with both duodenal ulcer (a high-acid state) and stomach cancer (a low-acid state). Paradoxically, patients who have duodenal ulcer are protected from developing stomach cancer. This implies that acid protects from the carcinogenic effects of *H. pylori*. Even in Japan, where stomach cancer is common, it is quite rare for a person with duodenal ulcer to develop the malignancy.<sup>69</sup>

One proposed explanation for this is the age of acquisition of the infection. In a tropical country where *H. pylori* is acquired in early childhood and nutrition may be poor, the infection causes severe damage to the acid-secreting area of the stomach.<sup>55</sup> Poor nutrition probably also assists this tendency to develop an asymptomatic low-acid state.<sup>70</sup>

Various factors are associated with the development of gastric cancer associated with *H. pylori* infection. These include the presence of hypochlorhydria due to infection, virulence of the infecting strain, genetic factors of the host, micronutrients in the diet, and geographical location of the patient. Thus, even if CagA toxin is present, the patient may never develop a duodenal ulcer but may be susceptible to gastric cancer in later life.<sup>3</sup>

If *H. pylori* is acquired in late childhood or in the adult years, then the infection tends to affect mainly the antrum of the stomach, leaving the acid-secreting part of the stomach (the corpus) intact. High acid secretion allows the development of duodenal ulcer disease.

# Lymphoma

*H. pylori* eradication therapy should be the initial step in the treatment of proven or suspected gastric lymphoma. Up to 90% of mucosa-associated lymphoid tissue (MALT) lymphomas are associated with *H. pylori*.<sup>71</sup> These indolent B-cell lymphomas are sometimes driven by continuing *H. pylori* antigenic stimulus and regress when *H. pylori* infection is treated.<sup>72,73</sup> Apparent cure of MALT lymphoma occurs in 70% of patients in whom *H. pylori* is eradicated.<sup>74</sup>

# DIAGNOSIS

The diagnosis of *H. pylori* may be by invasive or noninvasive methods, or both, as shown in Table 24-1. Endoscopic biopsy of gastric mucosa is the usual invasive method, although invasive methods can include blind biopsy, nasogastric aspiration, or the gastric string test.<sup>75</sup> Noninvasive tests are primarily serologic tests that detect IgG antibody to *H. pylori*, urea breath tests (UBT) to detect gastric urease, and fecal antigen tests.

# Invasive Tests

## Histology

For histologic study from intact mucosa, mucosal biopsy specimens are taken away from any visible lesion. This allows the pathologist to separate true inflammation (active chronic gastritis) from changes due to acute ulcer healing. Biopsies for

**Table 24-1 Accuracy of Diagnostic Tests for *Helicobacter pylori* Infection in 268 Patients Undergoing Esophagogastroduodenoscopy**

Tests	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Negative Predictive Value (%)
Invasive				
Biopsy: Chronic inflammation*	100	66.3	84.4	100

\*\*Data from Vaira D, Malfertheiner P, Megraud F, et al: Diagnosis of *Helicobacter pylori* infection with a new non-invasive antigen-based assay. HpSA European study group. Lancet 354(9172):30–33, 1999.

¶Serum antibodies to *H. pylori*.

Data from Cutler AF, Havstad S, Ma CK, et al: Accuracy of invasive and noninvasive tests to diagnose *Helicobacter pylori* infection. Gastroenterology 109:136, 1995.

*H. pylori* should be in addition to biopsies taken to exclude malignancy. At least two or, preferably, three biopsies need to be taken to detect *H. pylori* histologically. One biopsy can be taken from the greater curve of the antrum, one from the mid-corpus, and a third from the lesser curve angular notch.<sup>75</sup> In addition to routine H&E sections, the specimens should be stained with Giemsa or a silver stain such as Warthin-Starry or Genta stain.<sup>76</sup>

## Culture

Culture methods have been described earlier. Cultures may be moistened with a single drop of saline and transported to the laboratory in a sterile tube the same day. In some studies, organisms have remained viable in snap frozen biopsies.<sup>77</sup>

Culture has also been performed from blind gastric mucosal biopsies, from gastric aspirates, and from gastric string tests. These methods are less sensitive than culture of biopsies and are not widely used. Biopsy material, gastric mucus, and gastric juice can, of course, also be examined with polymerase chain reaction (PCR) or immunologic methods to detect *H. pylori*, but at present these are not reproducible in different laboratories and have no particular advantage over culture or histology.

## Urease Test

The ability of *H. pylori* to produce urease allows one to rapidly detect the organism in gastric biopsy material. Typically, the mucosal biopsy specimen is placed in a medium containing urea and a pH indicator. If urease (or *H. pylori*) is present, urea is converted to ammonia and the pH rises with a subsequent color change.<sup>78</sup> *H. pylori* is a prolific urease producer so that the reaction occurs in a few minutes in biopsies from infected patients. Since the test is so specific for

*H. pylori*, once a positive urease test has been noted, other diagnostic material is often unnecessary and may be discarded to save expense.<sup>79</sup>

## Noninvasive Tests

Infection is almost always accompanied by a rise in specific IgG antibody to *H. pylori*. IgM is present in some persons during the acute infection but has not been well studied because acute infections are rarely documented. IgA is present in 80% of persons with *H. pylori* so it can be used to diagnose the infection when present, but the absence of IgA does not exclude infection. Thus, in most cases, IgG is the best predictor of *H. pylori* infection (Fig. 24-5).

Tests to detect IgG come as a laboratory-based multi-well enzyme-linked immunosorbent assay (ELISA) kit, which is the most accurate serologic test. In properly selected patients, sensitivity and specificity reach 95%. In patients who have been treated for *H. pylori* infection in the preceding two years, IgG may remain positive and give an incorrect positive result even in persons who no longer have *H. pylori* infection.<sup>80</sup> For this reason the urea breath test is a better choice for follow-up. However, if carefully validated methods are used, serology can be used as a somewhat less accurate predictor of bacterial eradication. In Mexican patients, a 10% drop in ELISA absorbance at one year predicted *H. pylori* eradication in 84% of treated patients.<sup>81</sup>

A fecal antigen test for *H. pylori* is less sensitive than the urea breath test at detecting *H. pylori* after treatment, but fecal tests are ideal when the UBT is unavailable, and in very young children.

As well as being present in blood, small amounts of IgG may be detected in urine and gingival secretions. The latter two sources allow initial diagnosis from urine specimens and saliva.

**FIGURE 24-5** The natural history of *Helicobacter pylori* infection. The horizontal axis shows the time scale in days over 18 months. The left vertical axis is gastritis grade as represented in the columns showing antral and corpus mucosa inflammation graded 0 to 4. The right vertical axis shows the pH of gastric juice on a scale of 0 to 7. Note that corpus mucosa inflammation (hatched vertical bars) subsides after 3 months, whereas antral inflammation remains. As the corpus mucosa returns to near normal, acid secretion revives and gastric pH (dotted line) falls to normal acidic levels. Variable early responses are seen in IgA and IgM. IgG is present after the fourth week and remains as the most stable antibody response in nearly all infected persons.

**FIGURE 24-6** The urea breath test. Urea labeled with an isotope of carbon (a capsule of  $^{14}\text{C}$ -urea in this illustration) is swallowed by the fasted patient. Ten to 15 minutes later, a breath sample is collected into a balloon, processed as shown, and then counted in a scintillation counter.  $^{14}\text{CO}_2$  can be detected in the breath of a patient infected with *Helicobacter pylori*. When *H. pylori* is not present, the urea remains intact and there is no  $^{14}\text{CO}_2$  in the breath. Unchanged  $^{14}\text{C}$ -urea is excreted in the urine. Since more than 90% of the isotope is excreted within 3 days, radiation exposure is exceedingly small, about the same as natural background in 24 hours (0.3 mrem). In the  $^{13}\text{C}$ -urea breath test, the patient first swallows a high-fat meal or drink, which serves to delay gastric emptying. Ten minutes later, a baseline breath sample is collected and a solution of isotope is swallowed. Diagnostic breath samples are collected 20 to 40 minutes later. Breath samples are analyzed in an isotope ratio mass spectrometer.

### Breath Tests

Urea breath tests rely on the breakdown of isotope-labeled urea by urease (from *H. pylori*) in the stomach (Fig. 24-6). The  $\text{C}^{14}$  UBT only takes 10 minutes and requires a single breath sample. The  $\text{C}^{13}$  test takes 40 minutes and requires a baseline plus a 20–30 minute test sample. Both tests are highly accurate and the choice of which to use depends on availability and cost. Although the  $\text{C}^{14}$  UBT uses a trace of radioactive carbon, the dose is very small—equal to less than 24 hours of background exposure, so it is not excluded from use in women or children.<sup>82</sup>

### Diagnostic Criteria for Research Studies

Table 24-1 gives comparative data on the accuracy of various diagnostic tests as observed by Cutler and associates and Vaira and coworkers.<sup>83,84</sup> Although histology is accurate, these data reflect the results obtained by an expert pathologist with considerable experience in *H. pylori* diagnosis. Accuracy is quite variable among community pathologists, depending on their experience and the technical excellence of the staining methods used.

For clinical research, concordance between two different methods is necessary to prove the presence or absence of *H. pylori*. Good combinations for initial diagnosis would be histology and culture, urease test and culture, histology and serology, or urease test and serology.

In developing countries, noninvasive “indirect” methods of diagnosis are less helpful in demonstrating cure after therapy, probably due to frequent exposure and reinfection with

*H. pylori*. Positive serology in a highly endemic site frequently does not reverse. In addition, even “direct” tests such as UBT and stool antigen tests are more difficult to interpret due to false-positive results.

Proof of cure requires demonstration of sterile gastric mucosa, by two tests, 4 weeks after completion of therapy. Alternatively, two negative tests (UBT or fecal antigen) will suffice, the first at 4 weeks post therapy and the second at 6 to 8 weeks post therapy.

### TREATMENT OF *H. PYLORI* IN THE TROPICS

What is the role of treatment of *H. pylori* infection in the tropics? In many ways, treatment is similar to that in the United States, where eradication is prescribed for patients with peptic ulcer disease and the rare patient with gastric lymphoma.

In the tropics, regimens containing metronidazole are much less effective. Furazolidone is an alternative to metronidazole in a 10-day regimen that includes bismuth and amoxicillin. In some countries (i.e., Peru, Bangladesh, and Turkey), there is rapid recurrence even after successful eradication of *H. pylori* from the stomach. *Eradication* is defined as the absence of *H. pylori* at least 4 weeks after the last dose of antimicrobial therapy was given.<sup>6</sup> Reinfection is most likely caused by fecal contamination of water or food.

By sheer experience, several rules can be stated about eradication of *H. pylori*:

- In vitro sensitivity to an antibiotic does not predict in vivo efficacy. Therefore, use tested antibiotic combinations that are proven to work.

- Acid appears to protect *H. pylori* from antibiotics; therefore, the most successful treatments include strong acid suppression with proton pump inhibitors.
- Eradication rates peak between seven and 14 days of treatment. Do not use treatments shorter than seven days (cure rate is lower) or longer than 14 days (cure rate does not increase, but side effects increase).
- *H. pylori* does not develop resistance to the following drugs: amoxicillin, bismuth, tetracycline, and furazolidone. Therefore they may be reused, and sensitivity testing for them is not required.
- *H. pylori* quickly becomes resistant to the following drugs: metronidazole (and other "idazoles"), clarithromycin (and other "thromycins"), and rifabutin. Box 24-1 outlines doses used in therapy, while Table 24-2 gives treatment options.

## PREVENTION AND CONTROL

In developing countries, *H. pylori* recurrence after successful treatment occurs at rates 10 to 20 times higher than in developed countries. In addition, bacterial counts of *H. pylori* in gastric biopsies taken in recurrence are similar to those in biopsies taken prior to treatment. The high reinfection rate and lack of change in the *H. pylori* bacterial counts suggest there is little natural immunity after infection.

The rapid recurrence of *H. pylori* infection in some areas means that its treatment in impoverished tropical areas needs to be based on objectives that have a likelihood of some success. Goals for control of infection will have to be tempered with the additional need for improved sanitation. Thus, for example, antimicrobial treatment of the majority of the world's population living in tropical, developing areas to eradicate *H. pylori* for the purpose of preventing cancer would be unrealistic at present. On the other hand, prevention of gastric ulcer and duodenal ulcer recurrence for periods of a year or two might have some utility even where recurrence is high. Ethnic and cultural factors are also worth considering. For example, in Malaysia, prevalence rates among the Malays ranged from 12% to 29%, while the Chinese ranged from 27% to 58%, and Indians were between 49% and 52%.<sup>85</sup>

The role that treatment will have in reversing the progress of precancerous lesions to cancer is not known.

### Box 24-1 Treatments in Common Usage

- Omeprazole 20 mg BID, clarithromycin 500 mg BID, and amoxicillin 1 g BID (7–10 days)
- Omeprazole 20 mg BID, clarithromycin 250 mg BID, and metronidazole 400 mg BID (7 days)
- Bismuth (subsalicylate or citrate) 1 tablet QID\*, tetracycline 500 mg QID, metronidazole 250 mg QID (1 g to 1.5 g daily) (10–14 days)
- Rabeprazole 20 mg BID, amoxicillin 1 g BID, levofloxacin 250 mg BID (10 days)
- Omeprazole 20 mg BID, amoxicillin 1 g BID, furazolidone 200 mg BID, and bismuth subsalicylate (De-Nol) 240 mg (2 tabs) BID (14 days)

\*Addition of a proton pump inhibitor probably enhances the cure rate.

**Table 24-2 Treatment Options for *Helicobacter pylori*\***

Group	Description	Duration
A <sup>†</sup>	<b>Bismuth</b>	
	Ranitidine bismuth citrate (RBC) 400 mg BID	14 days
	Bismuth subsalicylate (Pepto Bismol) 525 mg (2 tabs) QID	14 days
	Bismuth subcitrate (DeNol) 120 mg (1 tab) QID	14 days
B	<b>Penicillin</b>	
	Amoxicillin 1 g BID	7 or 10 or 14 days
C	<b>Macrolide</b>	
	Clarithromycin 500 mg BID <sup>‡</sup>	7 or 10 or 14 days
	Josamycin 1000 mg BID	7 days
D	<b>Nitroimidazole</b>	
	Metronidazole 500 mg BID or TID <sup>‡</sup>	7 or 10 or 14 days
	Tinidazole 1000 mg daily	7 or 10 or 14 days
E	<b>Tetracycline</b>	
	Tetracycline 500 mg QID	14 days
F	<b>Quinolone</b>	
	Ofloxacin 500 mg BID	7 or 10 or 14 days
	Levofloxacin 250 mg BID	7–14 days
	Ciprofloxacin 500 mg BID	14 days
G	<b>Nitrofurans</b>	
	Furazolidone 200 mg BID <sup>‡</sup>	7 or 10 or 14 days
H	<b>Ansamycin</b>	
	Rifabutin 150 mg BID	14 days
I	<b>Proton Pump Inhibitors (use double a normal dose)</b>	
	Omeprazole 20 mg BID	
	Esomeprazole 40 mg BID	
	Lansoprazole 30 mg BID	
	Pantoprazole 40 mg BID	
	Rabeprazole 20 mg BID	

\*Treatment priorities are normally: IBC→IBD→IBEG. For penicillin allergy choose ICD or IAED→IFH.

<sup>†</sup>When Pepto Bismol is not available, substitute DeNol 1 tablet QID. RBC is not available in all countries.

<sup>‡</sup>Side effects are likely as doses of clarithromycin, metronidazole and furazolidone increase.

Evidence suggests that treatment may reverse dysplasia but not intestinal metaplasia. In patients with severe intestinal metaplasia associated with atypical changes or dysplasia, it is probably worthwhile at present to attempt to eradicate *H. pylori* from the mucosa. In patients with gastric lymphoma, a condition seen more commonly in developed countries, eradication is mandatory because tumor regression occurs when *H. pylori* infection is treated. There is no evidence to date, however, that eradicating *H. pylori* in patients with gastric cancer will affect the course except to prevent further new cancers.

Reinfection with *H. pylori* makes vaccine use highly attractive in some countries yet the high reinfection rates suggest that finding an effective vaccine may be quite difficult. Vaccines need to work in children to prevent early infection in order to protect against ulcer disease and gastric cancer. As noted previously, natural immunity to reinfection is weak, thus another possible use for the vaccine will be to prevent recurrence of *H. pylori* infection after effective antimicrobial therapy.

*H. pylori* infection is one of the most common infections in the tropics, significantly associated with peptic ulcer disease, gastric cancer, and possibly with other enteric infections. New diagnostic, therapeutic, and preventive measures will undoubtedly determine the evolving approaches to better controlling the consequences of *H. pylori* infections worldwide.

# Meningococcal Infections

W. MICHAEL SCHELD  
JAY D. WENGER  
ANASTACIO DE QUEIROZ SOUSA

## INTRODUCTION

Meningococcal infections continue to pose serious problems worldwide and are influenced by multiple factors, including geography, season, climate, serogroup, and population demographics.<sup>1,2</sup> Although focal outbreaks and epidemics occur in more developed areas, the incidence of epidemic meningococcal meningitis and meningococemia exhibits high geographic variability. The classic example is the so-called meningitis belt of sub-Saharan Africa (Fig. 25-1), where hyperendemic and epidemic meningococcal serogroup A disease occurs regularly (see later discussion).<sup>1,2</sup> Indeed, nearly 250,000 cases were recorded in this area in 1996, one of the worst outbreaks on record.<sup>3</sup> Meningococcal infections continue to pose an important public health threat in the tropics because mortality is unacceptably high and serious neurologic and other sequelae are not infrequent.

## History

The syndrome of epidemic meningitis with a purpuric rash was identified by Viesseux in 1805, who described an epidemic of “malignant purpuric fever” surrounding Geneva, Switzerland.<sup>4</sup> Danielson and Mann recorded the first observations of meningococemia and resultant meningitis in the United States in 1806 and many of the early descriptions were collated in a treatise by Elisha North of Connecticut in 1811.<sup>5,6</sup> Then, as now, the fulminant nature of some cases was frightening to physicians and laypersons alike; for example, the following was written by the Reverend Festus Foster of Petersham, Massachusetts, in a letter to the editor of *The Worcester Spy* dated March 6, 1811<sup>4</sup>:

I hasten to give you a sketch of the spotted fever in this place. It made its first appearance about the beginning of January last; but the instances were few and distant from each other, until last week. Although it had proved fatal in most instances, seven only had died belonging to this town previous to the 25th of February. Since that time the disorder has come upon us like a flood of mighty waters. We have buried eight persons within the last eight days. About twelve or fifteen new cases appeared on Thursday last; many of them very sudden and violent. This was the most melancholy and alarming day ever witnessed in this place. Seven or eight

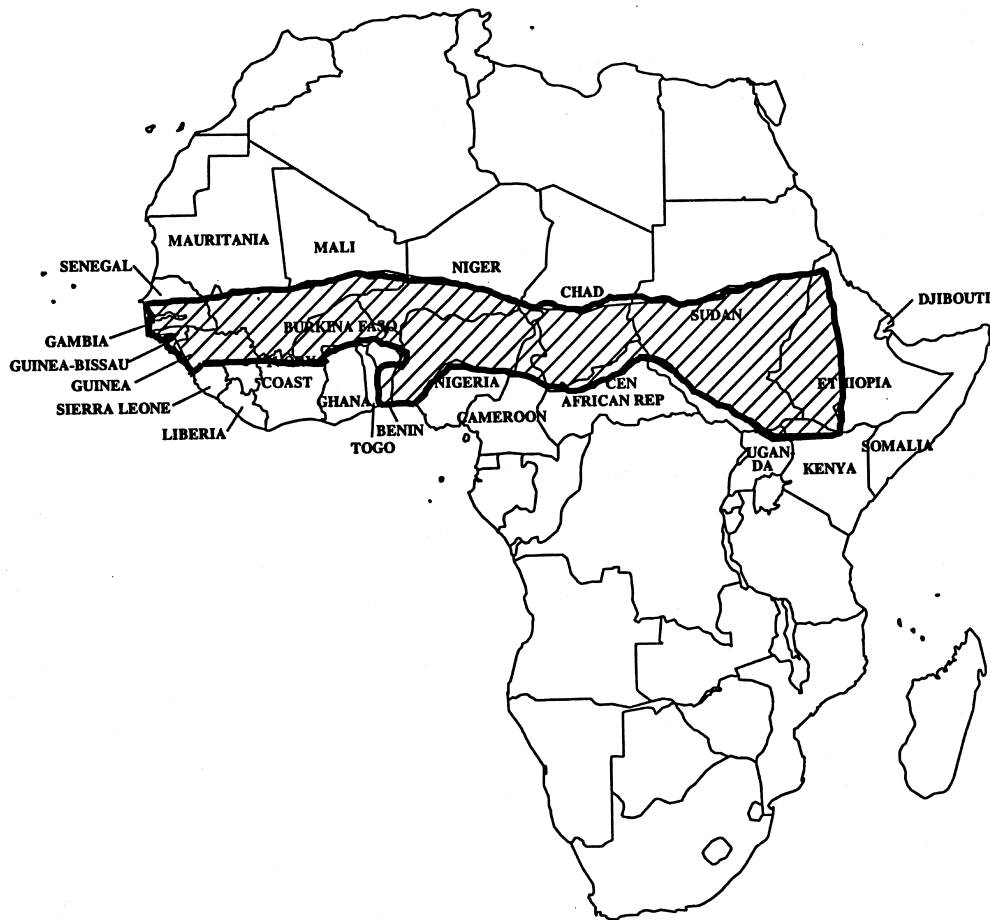

physicians were continually engaged in the neighborhood north of the meeting house, and I believe not one half hour passed in the forenoon without presenting a new case. Pale fear and extreme anxiety were visible in every countenance....

Anton Weichselbaum of Vienna first isolated meningococci in 1887. The organisms were obtained from the cerebrospinal fluid (CSF) of six patients with meningitis and were initially named *Diplococcus intracellularis meningitidis*. The lumbar puncture was introduced by Quincke in 1891 and the major CSF alterations associated with meningitis were well recognized by the turn of the century.<sup>4</sup> The first truly significant therapeutic modality for any form of meningitis was developed by Simon Flexner in 1913 and consisted of systemic and intrathecal administration of antimeningococcal antisera raised in horses. Although toxic, antisera therapy reduced the mortality of meningococcal meningitis from approximately 80% to 30% during World War I and for decades thereafter. The first successful account of therapy of meningococcal meningitis with an antimicrobial agent was published in 1937<sup>7,8</sup>; nine patients survived after receiving subcutaneous and intraspinal injections of sulfanilamide and the sole death occurred despite eradication of the organism from CSF. Although sulfonamide resistance among meningococci was common by the mid 1960s and led to the abandonment of this class of agents for the treatment and prophylaxis of meningococcal disease, this event spurred interest in the development of immunoprophylaxis, leading to several safe and effective meningococcal vaccines. Despite these achievements, serious meningococcal epidemics continue and the mortality associated with meningococemia remains significant despite the introduction of newer antimicrobial agents.

## AGENT

*Neisseria* species are non-spore-forming, oxidase-positive, nonmotile, gram-negative cocci (measuring approximately 0.8  $\mu\text{m}$  by 0.6  $\mu\text{m}$ ) that usually appear as biscuit- or kidney-shaped diplococci on smears of infected fluids. Since other organisms may appear similar morphologically, identification rests on biochemical and immunologic techniques. Sugar fermentation reactions are usually sufficient for speciation within the genus *Neisseria*.<sup>9</sup> Meningococci characteristically ferment glucose and maltose to acid. The organisms grow rapidly on blood, chocolate, gonococcal, or enriched Mueller-Hinton agar in a moist 3% to 10% CO<sub>2</sub> environment at 35°C to 37°C. A modified Thayer-Martin medium is employed for meningococcal isolation from contaminated sites, as in detection of the carrier state. The organism is rather fastidious, susceptible to drying and chilling, so all specimens should be inoculated promptly.

The ultrastructural characteristics of meningococci are complex. Surface components include capsular polysaccharide, fimbriae or pili, lipopolysaccharide (LPS), and outer membrane proteins (OMPs); several of these structures are important virulence determinants (see later discussion).<sup>4,9</sup> Major classification schemes of meningococci divide organisms into serogroups based on structural differences among capsular polysaccharides and agglutination reactions with specific antisera. Invasive isolates are uniformly encapsulated, whereas carrier strains are often unencapsulated (nongroupable). The serogroups have very

**FIGURE 25-1** The sub-Saharan Africa “meningitis belt.”

important epidemiologic and prevention-related implications. Thirteen serogroups are currently recognized<sup>4,9–11</sup> and designated A, B, C, D, E, H, I, K, L, X, Y, Z, and W-135. Most meningococcal disease is caused by organisms in serogroups A, B, C, and Y, although the proportion of cases caused by serogroup W-135 is increasing in some areas.<sup>4</sup> Recent epidemiologic trends for the three major serogroups are discussed in the following section.

Further classification of meningococci within serogroups into serotypes is based largely on the analysis of OMP profiles in the cell envelope.<sup>4,12</sup> Variations in protein *porB* are currently classified into serotypes 1 through 21. This classification scheme is useful in epidemiologic studies and as a basis for the preparation of subtype vaccines. Further classification into subserotypes is based on variations in protein *porA*.<sup>13</sup> Subserotypes P1.1 through P1.16 are currently recognized. Variations in LPS are utilized for subdivision into immunotypes (L1 through L12).<sup>1,10,14–17</sup> Techniques for subclassification of meningococci are generally available only in research or reference laboratories but are extremely useful in epidemiologic studies. In addition to classification by serogroup, serotype, subserotype, and LPS immunotype, many reports have focused on multilocus enzyme electrophoresis.<sup>18–21</sup> This latter technique led to the realization that epidemics caused on a worldwide basis by a strain of serogroup A meningococci are

derived from a single clone. The availability of the sequence of the meningococcal genome, coupled with the lack of serogroup B vaccine, has fostered the use of this database for the development of a noncapsular vaccine approach designated “reverse vaccinology.”<sup>22</sup>

## EPIDEMIOLOGY

### Transmission and Carriage

*Neisseria meningitidis* disease is exclusive to humans. No intermediate host, animal transmission, or reservoir has been proved. The human nasopharynx is the natural reservoir for meningococci; transmission is facilitated by airborne droplets or close personal contact. Meningococcal colonization may result in an asymptomatic carrier state (which is most common) or endemic, hyperendemic (i.e., in the meningitis belt between epidemics at approximately 10–50 cases per 100,000 per year), or epidemic disease.<sup>2,4,10</sup> Meningococci persist asymptomatically in the nasopharynx for periods ranging from several weeks to months to as long as 1 to 2 years.<sup>23</sup> During this colonization phase, protective antibodies to the strain are usually induced.<sup>24,25</sup> Carriage rates in most civilian populations range from 5% to 15%, but may be much higher in certain populations in which conditions conducive to outbreaks of

meningococcal disease exist, such as extreme crowding and mixing of populations in military recruit training camps. The implications of transmission and carriage on the pathogenesis and immunology of meningococcal disease are described later.

Although, as noted previously, at least 13 capsular serogroups of meningococci have been described, most human disease is caused by serogroups A, B, C, Y, and W-135, and these strains cause nearly all outbreaks of disease. This section describes recent epidemiologic trends for the major serogroups.

### Serogroup A

Serogroup A organisms are the most common cause of large epidemics.<sup>26</sup> These outbreaks may lead to incidence rates as high as 300 to 1000 cases per 10<sup>5</sup> population.<sup>2</sup> For example, the annual incidence reached 370 cases per 100,000 population in the greater São Paulo area in 1974, with 31,000 cases reported per year.<sup>1,2,4</sup> Attack rates are highest in children and young adults and some investigators have reported that, compared with the age distribution of disease in endemic cases, higher proportions of the disease occur in older children during epidemics.<sup>27,28</sup> Even with optimal treatment the mortality rate is still approximately 5% to 10% in patients with meningococcal meningitis<sup>29</sup> and approximately 20% of survivors have neurologic sequelae, including mental retardation and hearing loss.<sup>30</sup>

In some areas of the world, serogroup A meningococcal epidemics recur in a vaguely periodic pattern.<sup>26</sup> The African meningitis belt (see Fig. 25-1) is the best studied and the classic representative of this phenomenon. Although meningococcal infections were not recorded in the area until the 1880s, large outbreaks still occur regularly. The region, stretching from Ethiopia in the east to The Gambia in the west, frequently experiences epidemic disease and in some countries epidemics occur every 8 to 12 years. Figure 25-2 shows the incidence of disease and outbreak history in a typical meningitis belt country, Niger, for a 70-year period. This area of sub-Saharan Africa is dry with an average yearly rainfall of 300 mm and with winter seasons that feature warm,

dry, and dusty winds (the harmattan).<sup>26,31</sup> Outbreaks typically begin with the onset of the dry season in January and end abruptly with the coming of the rains in May or June.<sup>2,4</sup> Although conjectural, the distinct seasonality is striking and may be related to the drying effect on mucous membranes, seasonal transmission of respiratory viruses, or other factors.<sup>32</sup>

Olyhoek and colleagues<sup>18</sup> studied strains from epidemic waves from the 1950s through the early 1980s in an effort to assess the role of specific serogroup A meningococcal strains in these outbreaks. Individual epidemics and most waves of epidemics occurring over a number of years were invariably due to single strains. Although multiple strains could be identified during interepidemic periods, nearly all disease during outbreaks was caused by a single strain. No specific microbiologic characteristics were identified among the outbreak strains, which could account for the apparently increased virulence in epidemic potential, but this work suggests that strain characteristics are linked with epidemic disease.<sup>2</sup>

Major epidemics in the meningitis belt are heralded by a "shift to the right" toward older age groups (i.e., adolescents instead of 5- to 9-year-old children), a predictive feature of explosive epidemics in this area.<sup>4,10</sup> It is possible that introduction of new strains into populations that have not previously (or at least recently) been exposed to them leads to higher attack rates in older children compared to endemic or hyperendemic disease.<sup>2,20</sup> This could occur without assuming the new organisms have any inherent increased invasiveness or transmission potential. Introduction of newer strains with different antigenic determinants into the population places older children and young adults at risk since they have never "seen" this strain and may not be immunologically protected as they were from previously circulating strains.<sup>2,33</sup>

In 1996, the biggest wave of meningococcal meningitis outbreaks ever recorded hit West Africa.<sup>3</sup> An estimated 250,000 cases and 25,000 deaths occurred in Niger, Nigeria, Burkina Faso, Chad, and other countries and paralyzed medical care systems locally. The outbreak stopped with the spring rains as usual but continued into the next winter season.<sup>2</sup> The strain isolated was from the III-1 clone, which has

**FIGURE 25-2** The epidemiology of meningitis in Niger (a country located in the "meningitis belt") from 1919 through 1989. (From Riedo FX, Plikaytis BD, Broome CV: Epidemiology and prevention of meningococcal disease. *Pediatr Infect Dis J* 14:643, 1995.)

caused a series of outbreaks in Africa since 1988, according to the Centers for Disease Control and Prevention (CDC).

### Serogroup C

Large-scale outbreaks due to serogroup C have occurred frequently in the tropics in recent years. For example, the attack rate was 517 cases per 100,000 inhabitants during a serogroup C epidemic in Upper Volta (now Burkina Faso) in 1979 and recent studies documented an attack rate of 400 to 450 per 100,000 children up to 8 years of age in the Faroe Islands.<sup>4,10</sup>

Large serogroup A outbreaks such as those seen in Africa have not occurred in the developed world for over 2 decades.<sup>1</sup> In fact, in most developed countries, meningococcal disease in general, usually caused by serogroup B, C, or Y meningococci, has slowly decreased in incidence (Fig. 25-3). However, in the late 1980s and early 1990s, disturbing small outbreaks and an increased incidence of serogroup C disease were identified in a number of countries, particularly Canada.<sup>34,35</sup> The outbreaks usually involved between 5 and 20 children or young adults in small geographic areas and the fatality rate (10% to 15%) and burden of serious sequelae caused increasing alarm. Most of the recent Canadian outbreaks and cases were caused by one specific serogroup C strain, designated enzyme type ET-15.<sup>36</sup> This ET type increased in Canadian strain collections from 5% of all invasive isolates in 1985 to over 65% by 1990 and resulted in a large-scale immunization program (see later discussion). The ET-15 strain and four other closely related clonal strains were also implicated in a marked increase in outbreaks of serogroup C meningococcal disease in the United States, and this serogroup is among the most prevalent causes of meningococcal meningitis in that country (Table 25-1). Multiple outbreaks of serogroup C meningococcal disease have occurred recently and mass immunization campaigns were conducted in more than 10 separate sites between 1990 and 1993.<sup>34</sup> A clear increase in both recognized outbreaks and vaccine use for outbreak control occurred in the early 1990s. The U.S. outbreaks usually involved 5 to 15 persons in small communities or institutions, occurred with the same seasonal pattern as endemic disease (peak disease rates in the winter and early spring), were distributed widely over the country, and had a case-fatality rate that did not differ from the U.S. endemic disease rate observed previously.<sup>2,34</sup> Institutional outbreaks

tended to be of short duration, often with all cases occurring within 1 or 2 weeks, which differed from community-wide outbreaks, which tended to occur over a period of several months. Among community-wide outbreaks, affected persons tend to be older than those with endemic disease, again reflecting the possible introduction of strains of serogroup C meningococci that were “new” to the local populations. Indeed, this was confirmed by ET studies, which showed that 8 of the 13 most recent U.S. outbreaks were caused by closely related strains very similar to the Canadian ET-15.<sup>2,34</sup> These recent outbreaks have led to an increased understanding of the efficacy of the serogroup C meningococcal vaccine.<sup>37</sup>

### Serogroup B

Group B organisms, especially B:15:P1.16, have recently emerged as important pathogens in northern Europe, causing serious local outbreaks peaking in the 10- to 20-year-old age group. The continued high prevalence of serogroup B meningococcal disease has important implications because of the current lack of a widely available vaccine effective against this serogroup.

In the early 1990s, increasing rates of meningococcal disease in the general population and focal outbreaks were documented in Oregon.<sup>34,38</sup> The overall rate of disease, which had been in the range of 1 to 2 cases per 100,000 population, similar to that in the United States in general, rose steadily to

**FIGURE 25-3** The incidence of reported meningococcal disease in the United States by year, 1920–1995.

approximately 5 cases per 100,000. The age distribution in the cases also rose, consistent with epidemic disease caused by the other serogroups, but data soon showed that most of the cases were caused by serogroup B. Further subtyping data identified an enzyme type strain previously seen only very rarely in the United States, designated ET-301. This strain caused 80% of all serogroup B disease in Oregon (Fig. 25-4) and was closely related to other strains identified by Caugant and colleagues as the ET-5 complex.<sup>39,40</sup> Strains from this group have caused increased rates of disease, usually with overall incidence rates between 5 and 15 cases per 100,000 population per year in Norway, the Netherlands, Cuba, and throughout much of Latin America in the 1980s and early 1990s. In contrast to serogroup A and C outbreaks, which even in the absence of large-scale immunization programs usually run their course over a period of 2 to 3 years in a given area, serogroup B ET-5 outbreaks tend to cause prolonged elevations of disease rates in the same areas, persisting for up to a decade.<sup>41</sup> Although its precise origin is unknown, the ET-5 clone had marched through much of Europe, then through Latin America prior to its arrival in Oregon. The appearance of the ET-5 clone was gradual over many years as suggested by the disease rates, but the general epidemiologic pattern of disease was similar to endemic patterns in most respects, including seasonality, sex distribution (favoring males), and mortality rates. The shift in age distribution was again consistent with introduction of a new strain into an antigenically virgin population, as noted previously with

serogroup A and C outbreaks. In the absence of an effective vaccine and in order to evaluate the potential for other preventive measures, a study of risk factors for meningococcal disease was performed by the CDC and the Oregon and Washington state health departments.<sup>42</sup> Cases (120) and controls (250) were stratified by age above or below 18 years. Among those less than 18 years of age, the presence of a mother who smoked in the house was the overwhelming risk factor for disease, even when controlling for other socioeconomically related factors, including household crowding and educational status. Among those over 18 years of age, smoking or exposure to smoke was the only other significant risk factor in addition to underlying disease. A modifiable risk factor, smoking contributed strongly to disease acquisition in all age groups and suggests that 30% of all meningococcal disease in the outbreaks was attributable to smoking. Antismoking measures should be a useful public health measure during meningococcal outbreaks.<sup>2,42</sup>

Finally, as in the preceding discussion, meningococcal meningitis is primarily a disease of children and young adults. Fewer than 10% of cases occur in patients over 45 years old. Although meningococcal meningitis is unusual in this age group, 33% of sporadic meningococcal disease occurred in adults in a recent 5-year, population-based study from Atlanta.<sup>43</sup> Underlying conditions such as multiple myeloma, congestive heart failure, asplenia, and infection with human immunodeficiency virus (HIV) were prevalent in adults over 25 years of age with meningococcal infection but were unusual in

**FIGURE 25-4** Multilocus enzyme electrophoresis dendrogram of serogroup B meningococci showing the location of the enzyme type 5 (ET-5) complex.

the 18- to 24-year-old group (i.e., normal, nonimmunosuppressed persons).

## CLINICAL MANIFESTATIONS

The clinical manifestations of meningococcal disease can vary considerably, ranging from transient fever and bacteremia to fulminant disease with death ensuing within hours of the onset of symptoms. Wolfe and Birbara<sup>44</sup> described four major clinical syndromes:

1. *Bacteremia without sepsis*. In the setting of an upper respiratory illness or viral exanthem, blood cultures are drawn which are reported as positive for *N. meningitidis*, often after discharge. Occult bacteremia with recovery in the absence of antimicrobial therapy is rare, but serum concentrations of bacteria in children are often low, from 22 to 325 organisms per milliliter of blood in one report.<sup>45</sup>
2. *Meningococcemia without meningitis*. The patient is clinically septic with signs of malaise, weakness, headache, and hypotension developing shortly after admission or before in the presence or absence of skin rash and leukocytosis.
3. *Meningitis with or without meningococcemia*. Headache, fever, and meningeal signs predominate with a cloudy CSF. The state of the sensorium varies from fully alert to deeply obtunded. The deep tendon and superficial reflexes are unaltered and there are no pathologic reflexes.
4. *Meningoencephalitis*. Profound obtundation with meningeal signs and a cloudy CSF are characteristic. Furthermore, the deep tendon reflexes and superficial reflexes are either absent or, rarely, hyperactive and pathologic reflexes are frequently present.

Variations of these scenarios have been reported and the patient may progress from one to another during the course of disease.<sup>4,9</sup>

It is worth noting that the wide range of clinical expressions requires a high index of suspicion for meningococcal disease, especially in an endemic situation with sporadic cases. Meningococcal meningitis appears to differ somewhat from other forms of bacterial meningitis. For example, in a review of 53 cases of meningococcal meningitis by Carpenter and Petersdorf,<sup>46</sup> headache, confusion, and stiff neck occurred as symptoms in less than half of the patients. In infants and small children, fever and vomiting are often the only early clue to central nervous system (CNS) involvement, and these patients are frequently brought to the hospital only after an insidious impairment in consciousness or convulsions occur.<sup>9</sup> Evidence of meningeal irritation is common, except in the very young and very old. In classic early studies, Feigin and Dodge<sup>47</sup> observed that focal neurologic signs and seizures were less common in meningococcal meningitis when compared to pneumococcal meningitis or disease due to *Haemophilus influenzae*. Levels of consciousness across the spectrum were very similar with all three meningeal pathogens. Focal cerebral involvement in meningococcal meningitis is rare. The symptoms and signs of bacterial meningitis are listed in Table 25-2. With the preceding exception, meningococcal meningitis is similar to other forms of bacterial meningitis in presentation. Myalgias are particularly

**Table 25-2 Symptoms and Signs of Bacterial Meningitis**

Symptom or Sign	Percentage
Headache	≥90
Fever	≥90

Vomiting	≈30
Seizures	≈30
Focal neurologic findings	≈25
Myalgias	≈20
Ocular palsies	≈10
Hemiparesis	<5
Papilledema	<1

frequent in meningococcal disease and suggest this diagnosis over other bacterial pathogens. Focal findings, including cranial nerve deficits, are less frequent with meningococcal meningitis when compared with pneumococcal disease.<sup>4,9,47</sup> Finally, papilledema is rare in all forms of bacterial meningitis and suggests an alternative diagnosis.

Although petechiae progressing to purpuric lesions are a classic harbinger of meningococcemia with or without meningitis, some patients display a nonpetechial, nonpurpuric maculopapular eruption. These rashes, seen early in the syndrome, were described extensively by military physicians in the 1940s and 1950s.<sup>44,48</sup> The maculopapular rash resembles a viral exanthem, particularly rubella, and is evanescent, lasting hours to at most 2 days. Intense myalgias are often present during this rash. The petechial eruption is characterized by discrete lesions 1 mm to 2 mm in diameter, most frequently on the trunk and lower extremities, rapidly progressing to more extensive ecchymotic lesions (Figs. 25-5 and 25-6). Petechiae are common in pressure areas from clothing and rarely are vesicular or characterized by desquamation. Petechiae correlate with thrombocytopenia and coagulopathy, particularly disseminated intravascular coagulation (DIC). Response of petechiae early in the disease to therapeutic modalities is an important prognostic variable that can be assessed at the

**FIGURE 25-5** Early petechial rash in an adolescent with meningococcemia.

**FIGURE 25-6** Diffuse ecchymotic eruption in a case of meningococcemia.

bedside by proper attention to the number of lesions and progression within a defined area of the skin.<sup>4,9</sup>

Although the differential diagnosis is wide (Box 25-1), the presence of petechiae and fever with an altered sensorium is a medical emergency. Shock or the syndrome of purpura fulminans may dominate the clinical picture. Usually, the manifestations are of “cold shock” with peripheral vasoconstriction and cyanotic poorly perfused extremities in the presence of a diffuse purpuric eruption with systemic acidosis. The outlook is poor, especially when other complications, including the acute respiratory distress syndrome, DIC, renal failure, and myopericarditis, are present. The classic Waterhouse-Friderichsen syndrome is characterized by the following: (1) sudden onset of febrile illness, (2) petechial hemorrhages in the skin and mucous membranes, (3) cardiovascular collapse, and (4) DIC. Approximately 10% to 20% of meningococcal infections are dominated by this fulminant septicemia.<sup>4,9,49</sup>

Complications of meningococcemia and meningitis are related to shock and raised intracranial pressure, respectively. Other complications may be quite prominent and are somewhat unusual when compared with other forms of bacterial meningitis, including arthritis, pericarditis, myocarditis, conus medullaris syndrome, and cranial nerve palsies of the sixth, seventh, and eighth cranial nerves.<sup>9,47,50–54</sup> Pericarditis may be an immunologic reaction or secondary to toxins since many cases occur following bacteriologic eradication of the organism.<sup>55</sup>

#### **Box 25-1** Differential Diagnosis of Fever, Altered Sensorium, and Petechial Rash

Meningococcal disease  
 Rickettsial infections (e.g., Rocky Mountain spotted fever)  
*Staphylococcus aureus* endocarditis  
*Streptococcus pneumoniae*, *Haemophilus influenzae* (especially with splenectomy)  
 Septic shock  
 Viral meningitis  
 Viral hemorrhagic fevers  
 “Noninfectious”: thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), vasculitis, etc.

Pericardial involvement appears to be more frequent in the convalescent phase of the disease and in cases due to serogroup C meningococci.<sup>52</sup> Serious complications are often evident after eradication of the microorganism from blood and other body fluids. Myocarditis associated with meningococcal infection is manifested by a gallop rhythm, heart failure, pulmonary edema, and high central venous pressures in the face of poor peripheral perfusion. Cardiac glycosides are often prescribed, but evidence of therapeutic value is lacking. Although myocarditis is present in more than 50% of patients who die of meningococcal disease, clinically symptomatic heart failure is unusual. It does appear, however, that acute meningococcemia with myocarditis has a higher mortality rate than when this complication is absent.<sup>4,9,55</sup>

### **Respiratory Tract Infections**

Although nasopharyngeal colonization with meningococci renders sputum cultures hazardous in the interpretation of suspected meningococcal pneumonia, this syndrome has been recognized for more than 80 years.<sup>56,57</sup> Bacteremic meningococcal pneumonia is rare, and therefore blood cultures are often of no value. Serogroup Y organisms are often responsible for meningococcal pneumonia, although the recent emergence of serogroup Y strains in the Chicago area documented a variety of presentations out of proportion to pneumonia.<sup>58</sup> In a classic 1977 study utilizing transtracheal cultures to establish the diagnosis in U.S. Air Force recruits,<sup>59</sup> serogroup Y meningococcal pneumonia was characterized by a history of cough, chest pain, fever, chills, and a previous upper respiratory infection in more than 50% of patients. Rales and fever were nearly uniform and evidence of pharyngitis was present in over 80% of patients. Multiple lobar involvement was common (40%), but the right-lower and right-middle lobes were involved most frequently. No deaths occurred in this series of 68 patients.<sup>59</sup>

The association of meningococcal invasive disease with a preceding upper respiratory tract infection has been noted by many authors. Although common, the role of viral upper respiratory tract disease as a causal factor in systemic meningococcal disease remains problematic. Meningococcal clearance is clearly hindered in the presence of an upper respiratory tract infection, particularly influenza, but efforts at control of upper respiratory tract infections have only infrequently had an impact on the incidence of invasive meningococcal disease. Meningococcal pneumonia is unusual; for example, in a study of the cause of community-acquired pneumonia in Finland, this organism was isolated from only 6 of 162 cases.<sup>60</sup> In addition, the association of contact of cases with a prior symptom of upper respiratory tract infection has been implicated as a cause of serious meningococcal disease by several authors. The implication that inflammation in the nasopharynx is the predecessor to bacteremic disseminated meningococcal disease remains conjectural, but meningococcal disease incidence and severity both rise during influenza epidemics.<sup>61</sup>

A review<sup>62</sup> of 58 patients with meningococcal pneumonia over a 25-year period documented a shift in antimicrobial therapy from predominantly penicillin to cephalosporins; overall fatality was 8.6%. The serogroups responsible were as follows: Y, 44%; B, 18%; W-135, 16%; and C, 14%.

Fulminant meningococcal supraglottitis was first reported in 1995, with five more reports subsequently, and is characterized by fever, sore throat, muffled voice, and dysphagia with swollen supraglottic tissues seen on fiberoptic laryngoscopy, plain films, or cervical CT scans.<sup>63</sup>

### Meningococcal Urethritis

Meningococci have been isolated from the urethra and can be the etiologic agent in cases of urethritis.<sup>9,64</sup> Association with oral-genital sex and acquisition of the organism has been suggested. In homosexual males, the organism was isolated from the oral pharynx in 93% versus 6% from the rectum and only 1% from the urethra.<sup>65</sup> Nevertheless,  $\beta$ -lactamase-producing meningococci (although very rare overall) have been most often isolated from urogenital sources.

### Chronic Meningococcemia

This unusual syndrome, characterized by persistent meningococcal bacteremia associated with low-grade fever, rash, and arthritis, has been increasingly reported in recent years. The syndrome is very similar to that observed with chronic gonococcemia for which it is often mistaken.<sup>66</sup> Rimpalo and associates<sup>67</sup> compared the isolation of gonococci with that of meningococci from blood or synovial fluid cultures from 1970 to 1972 with similar studies from 1980 through 1983. The ratio of gonococcal to meningococcal isolates changed from 15:1 in the earlier period to 9:5 for the period 1980 to 1983. Systemic meningococcal infection should be considered in the patient with the acute arthritis-dermatitis syndrome, commonly ascribed to *Neisseria gonorrhoeae* (see Chapter 26).

### Meningococcemia in the Setting of Complement Deficiency

As discussed in the following sections, complement or properdin deficiency predisposes persons to the occurrence of systemic meningococcal disease.<sup>4,9,68,69</sup> Interestingly, the degree of severity of the meningococcal infection is often less and case-fatality rates are low when terminal complement components are affected. In all other respects, the clinical course is similar to that outlined previously. The specific complement and properdin deficiencies associated with systemic meningococcal infection are outlined in the following discussion.

### PATHOGENESIS AND IMMUNITY

As stated previously, meningococcal disease is exclusive to humans. The meningococcal carrier state is fundamental to the development of invasive disease.<sup>2,4,9,10</sup> Approximately 6% of the population develops nasopharyngeal colonization with *N. meningitidis* yearly. Nasopharyngeal carriage rates vary markedly with age and the population under study but are approximately 5% to 15%, rising from 0.5% in children 3 to 48 months old to approximately 20% to 40% in young adults. Carriage persists for weeks to months and occasionally years and largely accounts for the increased risk of disease in household contacts of an index case. Although uncharacterized host and environmental factors, including prior viral upper

respiratory tract infection, contribute to containment of infection or invasion, host immunity also plays an important role. Those persons recently colonized with meningococci appear to be at greatest risk of invasive disease.<sup>23</sup>

The age-specific incidence of meningococcal infection is inversely proportional to the presence of serum bactericidal antibodies against serogroups A, B, and C. More than 50% of infants possess bactericidal antibody at the time of birth as a result of transplacental transfer. Immunoglobulin G (IgG) antibody to serogroup B polysaccharide, however, is lacking in neonates. This contributes to the occurrence of serogroup B meningococcal disease in this age group, and since serogroup B meningococcal capsular antigen is identical to the capsular polysaccharides of *Escherichia coli* K1 and certain types of serogroup B streptococci, these organisms are also major causes of neonatal sepsis and meningitis.<sup>70</sup> The inverse link between occurrence of invasive disease and bactericidal antibody was first documented during an outbreak of serogroup C meningococcal meningitis among U.S. Army recruits in 1968.<sup>24</sup>

Although recovery from invasive meningococcal disease generally confers lifelong immunity against the homologous serogroup, this is not the major immunizing process. Nasopharyngeal colonization, particularly with serogroup B, C, or Y, may elicit the development of bactericidal activity, primarily directed against the colonizing strain but also active against heterologous organisms within 5 to 12 days of acquisition.<sup>4</sup> Nasopharyngeal colonization with nongroupable meningococci or *Neisseria lactamica*, virtually nonpathogenic organisms, may confer protective immunity against other meningococci with invasive potential. The carriage rates of pathogenic meningococci are far too low in children to account for antibody formation and the importance of other cross-reacting organisms, outside the genus *Neisseria*, has also been proposed. Paradoxically, an exuberant IgA response to meningococci may actually enhance the development of systemic disease.

In addition to bactericidal antibody, an intact complement system is also a component of the host's defenses against invasive meningococcal disease. Recurrent or chronic neisserial infections have been associated with rare isolated deficiencies of late complement components (C5, C6, C7, or C8, and perhaps C9).<sup>68,69</sup> Screening for complement defects is useful in families with recurrent or chronic neisserial infections and perhaps for individuals after only one episode of invasive meningococcal disease.<sup>71</sup> Complement deficiency also appears to predispose to meningitis caused by nongroupable meningococci and *Neisseria*-related bacteria (i.e., *Moraxella* or *Acinetobacter* species).<sup>72</sup> Depletion of early complement components (C1, C3, or C4) because of an underlying disorder such as nephrotic syndrome, hepatic failure, the presence of C3 nephritic factor, or multiple myeloma may predispose to the first episode of invasive meningococcal disease.<sup>4</sup> Properdin deficiency or dysfunction, with normal concentrations, also predisposes to invasive meningococcal disease; this defect is reversible with vaccination.<sup>68,73</sup> Asplenic states also increase the risk of serious infections by encapsulated organisms, especially *H. influenzae* or *Streptococcus pneumoniae*, but also meningococci. Although all of the preceding factors (particularly recent colonization with a pathogenic strain in a nonimmune host) undoubtedly contribute to the pathogenesis of overt meningococcal disease, the precise determinants

**Box 25-2** Putative Meningococcal Virulence Factors

Capsular polysaccharide

Lipopolysaccharide (endotoxin)  
Outer membrane proteins  
Outer membrane vesicles or blebs  
Metabolic pathways (e.g., iron)

contributing to the clinical illness (as opposed to the usual outcome of asymptomatic carriage) are poorly defined. Even during epidemics, only 1 in 1000 to 5000 colonized patients develops disease.<sup>4,10,23</sup> Various predisposing factors have been proposed to explain this discrepancy, including crowding, low socioeconomic status, poor general health, a preceding upper viral respiratory tract infection, and alcoholism.<sup>1</sup> Simultaneous outbreaks of meningococcal and influenza infections have been described in institutional and community settings.<sup>61</sup> The role of viral infections in the enhancement of meningococcal dissemination is unproved<sup>32,61,74</sup> and the precise factors that contribute to the development of overt clinical illness are at present poorly understood.

The time from nasopharyngeal acquisition to bloodstream invasion is short, usually 10 days or less. The incubation period may also be quite short, since “secondary” cases commonly occur within 1 to 4 days of the index case.<sup>4,9</sup> Once the organism is blood-borne, more than 90% of meningococcal disease is manifested as meningitis or meningococcemia. As noted previously, the clonal nature, even among clones of closely related organisms, suggests the complex interplay among virulence characteristics.<sup>4</sup>

The putative meningococcal virulence characteristics are listed in Box 25-2. As noted previously, all isolates from invasive infections are encapsulated (i.e., serogroup-positive), but 20% to more than 50% of isolates from carriers are unencapsulated (nontypable). The capsular polysaccharide appears to be essential to virulence, probably because of its antiphagocytic properties which allow the organism to escape host-phagocytic clearance mechanisms within the CSF or bloodstream. Pili are protein surface appendages composed of identical pilin repeated subunits and are very similar within the genus *Neisseria*. Cross-reacting antibodies bind to a short peptide sequence (residue 69–94) of gonococcal pili that is essential to receptor binding function, with perhaps a similar adhesion-promoting function among meningococci. Fresh meningococcal isolates from carriers and patients with clinical infection contain 7 to 40 pili per diplococcus.<sup>75</sup> Pili are important mediators of meningococcal adhesion to human nonciliated columnar nasopharyngeal epithelial cells,<sup>76</sup> an important early step in the development of the carrier state. Extracellular proteases that cleave the IgA1 heavy chain in the hinge region are elaborated by pathogenic *Neisseria* species (i.e., meningococci and gonococci). Although the role of IgA proteases in the pathogenesis of disease is controversial, these enzymes may promote invasion at the pharyngeal portal of entry. Meningococcal LPS resembles *H. influenzae* LPS by a lack of the O-antigenic polysaccharide side chain found in enteric bacteria despite a smooth phenotype

and proven virulence and is more properly referred to as a lipooligosaccharide (LOS). LPS is clearly important in the genesis of an array of the clinical manifestations of meningococcemia and meningitis.<sup>4,14,15</sup> Although the specific role for OMPs in meningococcal virulence is unclear, these organisms release substantial amounts of cell surface material in the form of outer membrane vesicles or blebs containing OMPs and LPS during growth in vitro and in vivo in the absence of cell lysis, a process exacerbated by antimicrobial agents. These outer membrane vesicles or blebs represent relevant vehicles for CNS tissue damage during meningococcal infection.<sup>77</sup> Finally, tissue invasion may also be facilitated by the ability of meningococci to obtain iron from transferrin, hemoglobin, and lactoferrin. Animals subjected to iron overload are more susceptible to fatal meningococcal infection.

**DIAGNOSIS**

Patients with a petechial or purpuric eruption, fever, and altered sensorium represent a medical emergency; the differential diagnosis is listed in Box 25-1. Between 50% and 75% of children with meningococcemia have a purpuric or petechial rash, principally on the trunk and lower extremities. Petechiae are found in the skin, mucous membranes, and conjunctivae but not in the nail beds.<sup>78</sup> A similar rash is sometimes seen on the trunk and extremities in echovirus type 9 meningitis, acute staphylococcal endocarditis, and rarely pneumococcal or *H. influenzae* meningitis, except in asplenic patients.<sup>79,80</sup> In the tropics, various viral hemorrhagic fevers (e.g., dengue, Crimean-Congo, Ebola) may present with fulminant ecchymotic lesions, fever, and altered consciousness. Rickettsial infections may also present with a similar picture. Petechial rashes should be promptly examined microscopically in the initial evaluation of a patient with suspected meningococcemia after aspiration or making a “touch preparation” on a glass slide; approximately 70% of these preparations will reveal the organisms usually within vacuolated neutrophils if meningococcemia is present (Fig. 25-7). In approximately 20% to 25% of patients with meningococcemia, the organisms

**FIGURE 25-7** “Touch prep” (impression preparation) of a petechial lesion in a case of meningococcemia, depicting the organisms and polymorphonuclear leukocytes (Giemsa stain).

**FIGURE 25-8** Buffy coat preparation of a peripheral blood smear in meningococcemia, displaying leukocyte-associated meningococci (Wright's stain).

may be visualized on the peripheral blood smear, especially in a buffy coat preparation (Fig. 25-8). Although the sensitivity is low, this simple test can be quite valuable in the initial approach.

The gold standard for the definitive diagnosis of invasive meningococcal disease remains culture of the organism from a normally sterile body fluid; the CSF and blood are the most common sites of positive cultures by the preceding techniques.<sup>4,9</sup> It is worth noting that CSF cultures are often positive in the presence of suspected meningococcemia, even in the absence of clinical signs of overt meningitis.<sup>81</sup> Meningococci are often cultured from CSF specimens that appear virtually normal by cytologic and chemical analyses in the early phases of illness. The mean concentration of meningococci in CSF specimens is approximately  $10^5$  colony-forming units (CFU) per milliliter with a wide range from approximately  $10^2$  CFU/mL to greater than  $10^7$  CFU/mL.<sup>82,83</sup>

The diagnosis of meningococcal meningitis requires examination of the CSF. As discussed previously, culture remains the gold standard and CSF Gram's stains in the presence of meningococcal meningitis have an overall sensitivity of approximately 70% in untreated patients. Other CSF values are highly variable. In an analysis of 58 patients with meningococcal meningitis,<sup>46</sup> the median leukocyte count was approximately  $1200/\text{mm}^3$ , with a range of less than  $10/\text{mm}^3$  to more than  $65,000/\text{mm}^3$ . Polymorphonuclear leukocytes predominate overwhelmingly in untreated patients. CSF protein concentrations range from 25 mg/100 mL to more than 800 mg/100 mL, with a median value of approximately 150 mg/100 mL, while 75% of CSF specimens reveal glucose concentrations below 40 mg/100 mL. All of these values may be altered significantly by prior antimicrobial treatment.<sup>4,9,46</sup>

Detection of meningococcal antigen in CSF by various techniques, including counterimmunoelectrophoresis, latex agglutination, and cold agglutination, have demonstrated variable sensitivity and specificity despite the capability of detecting 0.5  $\mu\text{g}$  or less of meningococcal antigen under standardized test conditions.<sup>9,82</sup> False negative results are common.<sup>84</sup> Meningococcal antigen may be detected in urine by these techniques despite negative CSF specimens. These tests should only be considered in Gram's stain-negative cases. CSF concentrations of lactic dehydrogenase or neuraminidase are

elevated in meningococcal meningitis.<sup>85,86</sup> Although the concentrations of these enzymes appear to be higher in meningococcal disease than in the other two major forms of bacterial meningitis, the utility of these tests in individual patient management is unclear.

Recently, the polymerase chain reaction (PCR) has been applied to the diagnosis of invasive meningococcal disease. For example, Ni and colleagues<sup>87</sup> examined 54 CSF samples with appropriate controls by PCR in a blinded fashion. The sensitivity and specificity of PCR for the diagnosis of meningococcal meningitis were both 91%. PCR may be most appropriate in Gram stain-negative cases, especially in patients receiving prior antimicrobial therapy, but requires special techniques and is expensive. Multiplex PCR has proven effective in the diagnosis of meningococcal disease, especially in the setting of prior antimicrobial administration.<sup>88,89</sup> The technique can be used to rapidly type strains of critical value in an evolving epidemic.<sup>40</sup> A more broad-based PCR technique utilizing 16sRNA may differentiate bacterial from viral meningitis, even in partially treated or Gram stain-negative cases,<sup>90</sup> but is not specific for meningococcal disease and not widely available. Nevertheless, in selected cases, PCR is a valuable adjunct for the diagnosis of meningococcal infections where resources are available. In most tropical regions during an epidemic, meningococcal meningitis is treated empirically without attempt at specific microbiologic or cytologic confirmation. Neuroimaging is virtually never indicated in suspected meningococcal meningitis or meningococcemia.

## TREATMENT AND PROGNOSIS

### Antimicrobial Therapy

Penicillin G 300,000 units/kg/day intravenously (IV), in divided doses every 2 to 4 hours, or ampicillin 300 to 400 mg/kg/day, in divided doses every 4 hours, are the preferred antibiotics for the treatment of invasive meningococcal disease.<sup>4,9,91</sup> A 5-day course of therapy is adequate for most cases of uncomplicated meningococcal meningitis (although some authorities recommend treatment durations of 3 days). Meningococcal resistance to penicillin has been reported.<sup>92</sup>  $\beta$ -lactamase-producing isolates are still very rare,<sup>93</sup> but penicillin-resistant strains that do not produce  $\beta$ -lactamase appear to have a reduced affinity for penicillin-binding proteins (e.g., PBP-2 and PBP-3) and have been reported from Spain, the United Kingdom, and other countries.<sup>94,95</sup> In Spain, the number of relatively penicillin-resistant meningococcal isolates reached 20% in 1989.<sup>94</sup> However, in the United States in 1991, only 3 of 100 isolates submitted to the CDC had minimum inhibitory concentrations (MICs) of penicillin of 0.125  $\mu\text{g}/\text{mL}$ .<sup>96</sup> Because of the low frequency of resistance in some areas, routine sensitivity testing of meningococcal isolates is not indicated; nevertheless, surveillance for resistance should continue. Meningitis due to relatively penicillin-resistant meningococci (MICs in the range of 0.1  $\mu\text{g}/\text{mL}$  to 0.8  $\mu\text{g}/\text{mL}$ ) has been managed successfully with currently recommended doses of penicillin or a third-generation cephalosporin (e.g., cefotaxime, ceftriaxone). These latter agents are preferred alternatives to penicillin; first- and second-generation cephalosporins and sulfonamides are unreliable.<sup>4,9,97-100</sup> Chloramphenicol is an effective substitute in the penicillin-allergic patient at a dosage

of 100 mg/kg/day up to a maximum of 4 g/day total dose,<sup>4,9,10</sup> as chloramphenicol-resistant meningococci, although reported, remain rare.<sup>101</sup> Chloramphenicol is often the preferred agent in resource-limited settings and is often administered in an oily vehicle by the intramuscular (IM) route to sustain chloramphenicol concentrations in blood over prolonged periods of time.<sup>4,10</sup> Recent studies in the United Kingdom have suggested that immediate administration by general practitioners of penicillin in the office setting as soon as the diagnosis is suspected may lead to improvement in the mortality rate.<sup>102,103</sup> Urgent administration of antimicrobial agents is indicated on suspicion of invasive meningococcal disease; prehospitalization administration may reduce mortality.<sup>104</sup>

## Supportive Care

Meningococcemia is often complicated by vascular collapse and shock. Multisystem organ failure is not infrequent. Meningococcal LPS is a potent toxin and initiates a cascade of events characterized by the release of multiple proinflammatory cytokines.<sup>105</sup> Girardin and coworkers<sup>106</sup> have demonstrated that serum concentrations of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 (IL-1), and interferon- $\gamma$  (INF- $\gamma$ ) correlate with the severity of meningococcemia in children. Waage and associates<sup>105,107–109</sup> studied this problem extensively during the recent epidemics in Norway. It is clear that high serum concentrations of IL-6 and IL-1 are associated with a fatal outcome in children. IL-1 was exclusively detected in patients with high concentrations of IL-6, TNF- $\alpha$ , and LPS and a rapidly fatal outcome. Extensive complement activation also occurs in fulminant cases of meningococcemia. Complement activation products in concert with other mediators may contribute to multisystem organ failure and death in severe cases. Despite this newfound knowledge, adjunctive therapy with specific polyclonal or monoclonal antibodies to proinflammatory cytokines remains investigational at the time of this writing and is of unproven benefit in fulminant meningococcemia.<sup>110</sup> Despite the suggestion that the Waterhouse-Friderichsen syndrome is mediated in part by adrenal hemorrhage, the use of corticosteroids remains controversial. Although corticosteroids may be of benefit in some forms of bacterial meningitis, high doses are associated with a worse outcome in sepsis and septic shock. In suspected invasive meningococcal disease, corticosteroids are best avoided.<sup>111</sup> In addition, the routine use of heparin in the therapy of DIC is not recommended. Some authorities recommend heparin if the patient is actively bleeding; the benefit of this approach remains unproved and may be harmful.<sup>9,112,113</sup> The administration of heparin did, however, appear to reduce the complications of digit and extremity necrosis, a dreaded complication, in a small noncontrolled series of patients with purpura fulminans<sup>114</sup> and deserves further evaluation. Other major life-threatening processes such as renal failure; systemic acidosis; the acute respiratory distress syndrome; meningococcal pneumonia; nosocomial pneumonia due to aspiration; and neurologic sequelae, including coma, diabetes insipidus, and raised intracranial pressure, may need to be addressed during the acute phase. Obviously, these problems are best approached in the intensive care unit environment.<sup>4,9,98–100</sup> During epidemics, such complications may easily overwhelm public health resources in resource-limited settings. Pericarditis may occur insidiously

in the convalescent phase of the illness. Meningococci are not usually found in the pericardial fluid, and cardiac tamponade is unusual.<sup>52</sup>

Despite aggressive supportive care and the administration of appropriate antimicrobial agents, the outcome for patients with fulminant meningococcemia is often poor. A modality that deserves further study is plasmapheresis. This technique has been attempted, although on an extremely limited scale, in desperately ill patients and may lead to a rapid decrease in serum TNF- $\alpha$  concentrations and improved mortality and morbidity rates.<sup>115</sup> Although controlled clinical trials have not been performed, the outcome in the severely ill patients studied in these trials is much better than expected when compared with historical controls. Venovenous diafiltration or extracorporeal membrane oxygenation has also been utilized, apparently with some success, in meningococcemia,<sup>116,117</sup> but these techniques also remain experimental at this time. However, administration of the N-terminal fragment of recombinant bactericidal permeability increasing (rBPI21) protein improves functional outcome of children with meningococcemia, but the study was not large enough to detect a mortality benefit.<sup>118</sup>

Meningococcemia results in profound depletion of serum protein C concentrations. Administration of recombinant protein C may limit the extent of tissue necrosis (and reduce mortality),<sup>119</sup> but further data is needed. This modality is expensive, precluding use in many areas.

Prognostic indicators for the outcome from meningococcemia have been evaluated. One system developed by Kornelisse and colleagues, based on serum potassium, platelet, and C-reactive protein concentrations, and base excess, predicts survival or death in 86% of patients.<sup>120</sup>

Finally, meningococcemia is associated with supranormal plasma concentrations of plasminogen activator inhibitor (PAI-1). Children with a functional deletion/insertion (46–56) polymorphism in the promoter region of PAI-1 produce higher concentrations and are at increased risk of coagulopathy and death from meningococcemia.<sup>121</sup>

## PREVENTION AND CONTROL

### Chemoprophylaxis

Following the documented efficacy of sulfonamides for therapy of meningococcal meningitis, it became apparent that these agents could eliminate the carrier state for prolonged periods.<sup>9,100</sup> Eradication of the carrier state during epidemics led to a decline in the number of cases.<sup>48</sup> Chemoprophylaxis to prevent “secondary” cases is now well established. Unfortunately, following a serogroup B meningococcal epidemic at Fort Ord, California, in 1963 and the widespread recognition of sulfonamide resistance, this group of agents is no longer reliable. Similarly, other agents active against meningococci *in vitro* have been tested and have failed to eradicate the carrier state, including erythromycin, trimethoprim, cephalexin, nalidixic acid, and oxytetracycline. Many authorities have hypothesized that eradication of the carrier state is dependent on achieving bactericidal concentrations in tears and saliva.<sup>122</sup>

Several agents reliably eradicate the carrier state, although for a varying duration of time. Minocycline eradicates the carrier state rapidly and eradication persists for up to 6 to 10 weeks after treatment.<sup>9,123</sup> Unfortunately, vertiginous reactions limit

the usefulness of this agent. Rifampin is also highly effective but can result in the emergence of rifampin-resistant meningococci in approximately 10% to 27% of the patients receiving this agent.<sup>124</sup> Ciprofloxacin, ofloxacin, and azithromycin<sup>125</sup> have been shown in controlled studies to eradicate nasopharyngeal carriage following a single dose for up to 1 month in a high proportion (95% or more of subjects).<sup>126,127</sup> Similarly, a single dose of ceftriaxone (250 mg IM in adults and 125 mg for children under 15 years of age) is also highly effective.<sup>128</sup> Currently, rifampin is the recommended therapy for meningococcal prophylaxis at a dosage of 600 mg every 12 hours in adults and 10 mg/kg every 12 hours in children (both for 2 days).<sup>9</sup> This recommendation also concludes that quinolones and ceftriaxone in a single dose are highly effective and compliance is assured.<sup>129</sup>

The group at greatest risk of secondary cases of meningococcal disease includes household contacts of the index case and these persons should certainly receive chemoprophylaxis. Similar high-risk situations occur in closed populations, including college dormitories, military barracks, nursery schools, day-care centers, and chronic care hospitals.<sup>130</sup> The use of chemoprophylactic agents in these groups should be individualized based on the intensity of exposure. Health-care personnel rarely require chemoprophylaxis except when intimate contact (such as mouth-to-mouth resuscitation)<sup>48</sup> with the index patient is performed.<sup>131</sup> Exposure to cases of meningococcal pneumonia is usually recognized too late to afford protection to health-care workers through chemoprophylaxis. The index case should also receive chemoprophylaxis prior to leaving the hospital if treated with penicillin or ampicillin, as these agents do not predictably eliminate the carrier state.

### Immunoprophylaxis

Shortly after the recognition of sulfonamide-resistant meningococci, and the obvious implications for prevention of secondary cases through chemoprophylaxis, efforts to develop immunogenic vaccines against the major meningococcal serogroups intensified.<sup>132</sup> While immunity is variable following vaccination, no current commercially available meningococcal polysaccharide vaccine is immunogenic in children under 24 months of age and therefore chemoprophylaxis is a primary strategy in day-care centers. Conjugate vaccines are urgently needed (see later discussion). Large-scale studies have clearly documented the immunogenicity and protective efficacy of vaccines against serogroups A and C meningococci. The use of these vaccines in developing countries has markedly increased in recent years, as discussed in the following sections.

#### Serogroup A

Gotschlich and coworkers<sup>133</sup> conclusively demonstrated the protective activity of bactericidal antibody against capsular polysaccharide. Serogroup A polysaccharide vaccines seem to be immunogenic in older children and adults, but are unreliable in children less than 2 years of age. In addition, protection from a single dose is limited to less than 3 years in children who receive the vaccine between the ages of 1 and 4 years.<sup>27,134</sup> In older children, efficacy declines slowly over 3 years but long-term duration has not been studied. Thus, routine infant

immunization has never been recommended with these vaccines<sup>135–138</sup> and their primary use has been in emergency campaigns.<sup>139</sup>

For maximum efficacy, emergency mass immunization of populations at risk requires early recognition of the outbreak and rapid mobilization of immunization. Thus, markers of outbreaks are critically needed at the local level quickly. Moore and colleagues<sup>140</sup> evaluated the pattern of meningococcal epidemics in Burkina Faso and found that 2 consecutive weeks of 15 cases per 100,000 population was a good early predictor of a major outbreak and could be used to trigger immunization. As shown in Figure 25-9, mass immunization of a population in Nairobi, Kenya, prevented a large number of cases, but many more cases could have been prevented if immunization had been started earlier. This concept has now been integrated into an emergency response plan by the World Health Organization (WHO), which outlines necessary steps to accurately identify and respond to outbreaks.<sup>139</sup> Even with accurate detection and rapid response, however, it is estimated that only about 60% of outbreak-related cases can be prevented by this strategy. Prevention of additional cases, and ultimate prevention of outbreaks altogether, require more effective vaccines.

Following the example provided by the *H. influenzae* type b conjugate vaccines, preparations of serogroup A, C, or W-135 polysaccharide chemically conjugated to proteins have been evaluated in clinical trials.<sup>141–144</sup> Conceptually, the conjugated product will perform as a T cell dependent antigen, which induces larger immune responses in infants, primes immunologic memory, and can lead to booster responses with subsequent doses. The introduction of similar conjugated vaccines into routine immunization programs in Africa appears to be the only effective way to prevent future epidemics. Indeed, this approach has already proven feasible. Chemoprophylaxis is impractical in resource-limited settings (e.g., the sub-Saharan meningitis belt) to control meningococcal disease. The first major worldwide epidemic of serogroup W-135 disease followed the hajj (the annual pilgrimage of Muslims to Mecca) in 2000 and spread throughout areas of Africa (e.g., Burkina Faso) and Europe through 2002. A conjugate vaccine, developed and deployed rapidly against serogroups A, W-135, and C produced a dramatic decline in cases during 2003 to 2004.

The meningococcal vaccine project, a collaboration of the WHO, CHI/Path, and the Gates Foundation, with a new manufacturer (the Serum Institute of India) is on target to produce a cheap (approximately 40¢/dose) serogroup A meningococcal conjugate vaccine by 2009. The goal is to target high-risk groups, ages 1 to 29 years, in 18 countries, a total population of approximately 270 million.

#### Serogroup C

The serogroup C polysaccharide vaccine shares many of the characteristics of the serogroup A polysaccharide vaccine (in the United States, the only licensed meningococcal vaccine is a combination of serogroups A, C, Y, and W-135 antigens, but monovalent A, monovalent C, and bivalent A–C are available in other areas). Again, the serogroup C vaccine is not effective in children less than 2 years of age.<sup>129</sup> In addition, 7 to 10 days is required following immunization to reach appreciable antibody levels, so rapid immunization is essential to maximize

**FIGURE 25-9** The epidemic curve from a serogroup A meningococcal disease epidemic in Nairobi, Kenya, in 1989. The solid line shows the actual number of cases that occurred by week, including those that occurred after mass immunization campaigns. The hatched line shows modeled data with the estimated number of cases that would have occurred without any vaccination program. The space between these two lines represents the number of cases actually prevented. However, the dotted line shows modeled data of the number of cases that would have been prevented if immunization had been carried out according to the time line set forth in the current WHO guidelines and clearly shows that a much larger number of cases were preventable by mass vaccination. (From Pinner RW, Onyango F, Perkins BA, et al: Epidemic meningococcal disease in Nairobi, Kenya—1989. *J Infect Dis* 166:359, 1992; and unpublished data from the Centers for Disease Control and Prevention, Atlanta, GA.)

impact in an epidemic. Serogroup C outbreaks, such as those described earlier in Canada, usually involve a small number of individual cases, so that recognition of the outbreak and accurate characterization of a population at risk are difficult. The advisory committee for immunization practices has recently addressed many of these issues in guidelines for the control of serogroup C outbreaks.<sup>129</sup>

Although the efficacy of serogroup C vaccines has been clearly established in studies of U.S. Army recruits by Artenstein and associates,<sup>145</sup> the efficacy and impact of large-scale immunization campaigns for serogroup C meningococcal disease following local focal outbreaks in the United States and Canada have been difficult to evaluate. However, in several instances, additional cases occurred in the same population during the next meningococcal disease season, which raises questions about the utility of immunization campaigns and the assessment of the efficacy of the vaccine delivered in this fashion.<sup>2</sup> For example, in Gregg County, Texas, high rates of disease occurred for three consecutive years in spite of large immunization programs. A case-control study revealed that the vaccine was 85% protective, but additional studies demonstrated only a relatively small proportion of the population at risk had received vaccine in the early mass campaigns, leaving a large segment of the population unvaccinated.<sup>146</sup> This illustrates the lack of herd immunity following meningococcal vaccination; current preparations protect only those who receive the vaccine. Complete immunization coverage with a polysaccharide vaccine approach is critical to halting epidemic disease. As with serogroup A disease, conjugate serogroup C meningococcal vaccines promise to provide a means to prevent not only

epidemic but also endemic infections.<sup>142</sup> The experience with serogroup C conjugate vaccine in the United Kingdom is illuminating. Although rates vary widely in Europe, the annual incidence of meningococcal disease in the United Kingdom is higher than in the United States (e.g., approximately 3–5 cases/100,000 population/year vs. 1.0–1.5 cases/100,000 population/year). In 1997, the serotype distribution in the United Kingdom was as follows: B, 54%; C, 38%; other, 8%; and most deaths due to serogroup C occurred in children less than 2 years of age and in adolescents 15 to 20 years old. Licensed serogroup C vaccines have conjugated the polysaccharide to CRM-197 mutant diphtheria toxin or tetanus toxoid.<sup>147</sup> The former was launched in the United Kingdom in 1999 (approximately 18 million doses in children less than 18 years of age from November 1999 through October 2000). Routine vaccination was offered at 2, 3, and 4 months of age with varying schedules in older children. High serum bactericidal titers (e.g., greater than 1:8) correlating with efficacy were induced by 4 months of age with a brisk memory response evoked upon booster administration after 1 year. The vaccine efficacy was an approximately 90% reduction in serogroup C disease in the vaccinated group,<sup>148</sup> while no change in serogroup B disease occurred in the United Kingdom overall. In addition, carriage was reduced (although low)<sup>149</sup> and invasive disease declined approximately 67% in the unvaccinated older population.<sup>150</sup> Although this approach is extremely promising, vaccine efficacy was lost greater than 1 year after vaccination in the 2, 3, and 4 month target group when examined 4 years afterward.<sup>151</sup> It is hoped that changes to this “accelerated” schedule and/or uniform boosters will reverse this trend.

## Serogroup B

Since the polysaccharide antigen of serogroup B meningococci displays cross-reactivity with human neural tissue, development of vaccines based on the polysaccharide antigen has proved exceedingly difficult and, indeed, there is currently no vaccine available for the prevention of serogroup B disease. There is likely a strong immunologic tolerance to the presentation of this antigen.<sup>152</sup> Thus, efforts to create a serogroup B vaccine have been recently directed at the OMPs of the organism. Although several candidate vaccines have been prepared which display moderate efficacy in older children, efficacy in children less than 4 years of age has not been shown, and this is a major problem for widespread use of the vaccine.<sup>153–156</sup> In addition to OMP vaccines and polysaccharide-protein conjugates, other approaches to the development of new vaccines against meningococci are currently under study, including vaccines developed to detoxify lipooligosaccharide, an anti-idiotypic antibody approach, novel surface proteins, peptide mimics, or a mucosal vaccine approach.<sup>9,132,157,158</sup>

Many other meningococcal polysaccharide-conjugate vaccine are under development. Aventis has produced a quadrivalent (A, C, Y, W-135) meningococcal polysaccharide vaccine conjugated to 48 µg of diphtheria toxoid (Menactra) and have submitted a New Drug Application to the Food and Drug Administration targeting persons ages 11 to 55 years in the United States. The vaccine is expensive (estimates \$70–\$80/dose exclusive of administration costs) and does not protect the youngest, most vulnerable group (e.g., less than 1 year of age). The advisory committee on immunization practices is evaluating further data on efficacy, pharmacoeconomics, target populations, implementation, and so forth. Other approaches have complexed meningococcal conjugates to established antigens for potential routine childhood immunizations (e.g., DTPw-hepatitis B-HiB-meningococcal serogroups A and C or Hib-meningococcal serogroup C). These have been developed by major multinational pharmaceutical firms and expense may prelude widespread uptake in resource-limited settings.

# Gonococcal and Other Neisserial Infections

PETER LEONE

## INTRODUCTION AND THE AGENT

The sexually transmitted disease commonly known as gonorrhea is caused by the bacterium *Neisseria gonorrhoeae*. *N. gonorrhoeae* is a gram-negative diplococcus that is aerobic, nonmotile, and non-spore-forming. It belongs to the family Neisseriaceae, which contains the genera *Neisseria*, *Moraxella*, *Eikenella*, *Simonsiella*, *Alysiella*, *Kingella*, and *Acinetobacter*.<sup>1</sup> The genus *Neisseria* is composed of 10 species, all of human origin. Despite their human origin, two of these species are pathogenic to humans: *N. gonorrhoeae* and *N. meningitidis*.<sup>2</sup> The latter is an etiologic agent of a common form of bacterial meningitis (see Chapter 25). *N. gonorrhoeae* is the cause of urethritis, cervicitis, pelvic inflammatory disease (PID), and associated infections and is distantly related to *Neisseria lactamica*, which can occasionally be a human pathogen. All *Neisseria* species are oxidase-positive, but only *N. gonorrhoeae* typically invades the upper reproductive tract; 20% of women with gonococcal cervicitis develop PID.<sup>3</sup> Gonorrhea is occasionally invasive, and 0.3% to 3.0% of mucosal infections progress to disseminated gonococcal infection (DGI).<sup>4</sup> Perhaps the most important impact of gonorrhea is facilitation of acquisition of human immunodeficiency virus (HIV)<sup>5,6</sup> and shedding of HIV in semen.<sup>7</sup>

## EPIDEMIOLOGY

Although the overall incidence of gonorrhea has declined since 1975, it remains the second most commonly reported communicable disease in the United States. The case rate of U.S. gonococcal infection decreased from 371.5 per 100,000 population in 1986 to 116.2 per 100,000 in 2003.<sup>8</sup> The 2003 rate is the lowest ever reported for the United States. Even with the continued decline in the gonorrhea rate, the rates remain high regionally—in the Southeast; among some ethnic groups—African Americans and Hispanics; and among certain behavioral risk groups—men who have sex with men (MSM), as well as adolescents.<sup>8</sup> The highest incidence of gonorrhea occurs in adolescents and young adults.<sup>9</sup> In 2003, 15- to 19-year-olds showed the highest rate among females while 20- to 24-year-olds had the highest rates among males.<sup>8</sup>

These elevated rates may reflect their greater number of partners, the higher likelihood of unprotected intercourse, and choice of partners, who themselves have a higher incidence of disease. A recent population-based survey of adolescents in the United States found relatively low overall prevalence of gonorrhea, 0.43%, with little variation in prevalence by sex or age but substantial differences by ethnicity. The prevalence rate for African Americans was approximately 2%, which was 36 and 14 times greater for white men and women, respectively.<sup>10</sup>

The global incidence of gonorrhea remains high with an estimated 62 million new cases each year.<sup>11,12</sup> Rates for the disease remain low in most of Europe and are relatively higher in developing countries. Importation of gonorrhea from other countries accounts for 14% to 25% of cases of gonorrhea diagnosed in Europe.<sup>13</sup> Accurate information on the incidence and prevalence of gonorrhea is lacking for most of these countries. Gonococcal infection is often underdiagnosed and underreported. Infection distribution is uneven with the highest rates in sub-Saharan Africa, South and Southeast Asia, the Caribbean, and Latin America. This is also true in developed countries where prevalence is highest in the most marginalized individuals socially and economically. Prevalence studies suggest that lower socioeconomic factors, ethnic minority status, and younger age are major determinants of disease acquisition.

Poverty is a risk factor for gonorrhea, as indicated by the higher rates of disease in the rural southern United States, large inner cities, and within minority groups.<sup>9</sup> Impoverished groups often have limited access to health care, are reluctant to seek prompt treatment for disease, may engage in drug or substance abuse, and often populate concentrated areas with high disease rates. In the United States, poverty is often reflected by minority status, which helps explain higher disease rates within various ethnic groups. In 2003, African Americans accounted for 70.7% of total reported cases of gonorrhea in the United States.<sup>8</sup> The rate of gonorrhea for African Americans was 20 times higher than among whites in 2003 (655.8 cases per 100,000 vs. 32.7). The infection rate of gonorrhea among American Indian/Alaskan natives (103.5) and among Hispanics (71.7) was 3 and 2 times higher, respectively, than the rate among non-Hispanic white Americans.<sup>8</sup> These disparities in reported rates of infection further illustrate the greater impact of gonorrhea on minority groups.<sup>9,14</sup> Ethnicity itself is not a risk factor but rather a surrogate marker for social and behavioral factors. If these factors were more easily quantifiable, they could be more clearly separated from the larger category of ethnic background.

## Transmission

Gonorrhea may be the sexually transmitted disease (STD) most efficiently spread from person to person. Transmission following a single episode of vaginal intercourse is approximately 70% to 80% from male to female and 20% to 30% from female to male.<sup>15,16</sup> Transmission through either receptive or insertive rectal intercourse may be less efficient than by vaginal intercourse. Oral-genital transmission is probably the least common and least efficient means of transmission. Although specific rates are not available, it has been reported that transmission is greater through fellatio than cunnilingus.<sup>17</sup> In MSM, oral-genital

contact may account for up to 50% of all urethral infections. Consequently, oral-genital contact can be viewed as a risk factor for acquisition of urethral gonorrhea.<sup>18</sup>

As with other STDs, gonorrhea prevalence and transmission can be partially explained by applying the concept of “core group” transmitters. By definition, members of the core group are individuals who are more likely to become infected and more likely to transmit the disease to others. As a result of their high level of sexual activity and frequency of partner change, these individuals have the greatest influence in sustaining the epidemic of gonorrhea.<sup>19</sup>

## CLINICAL MANIFESTATIONS

The clinical manifestations of gonorrhea are numerous and vary from local asymptomatic disease to dissemination. The initial site of infection, the infecting strain of gonorrhea, host immunity, and other coinfections all influence the spectrum of clinical disease experienced by the patient.

### Gonococcal Infection in Men

In men, gonococcal urethritis is the most common manifestation of infection. Following inoculation of the anterior male urethra, *N. gonorrhoeae* attaches to and infects columnar epithelial cells. The incubation period may range from 24 hours to 14 days, but 75% of men develop symptoms (dysuria and discharge) within 4 days of infection.<sup>20,21</sup> Dysuria usually precedes the development of purulent discharge by approximately 24 hours. Although 90% of newly acquired infections are symptomatic, about 50% of all infections in the community have few to no symptoms.<sup>22</sup> If left untreated, gonococcal urethritis usually resolves over the course of several weeks, with the majority of cases becoming asymptomatic within 6 months.<sup>23</sup>

Since the widespread availability of effective antimicrobial therapy in the 1940s, local complications in men have become rare. Local complications do occur, however, as evident from the gonococcal cause of about 10% of acute epididymitis. Other complications include acute or chronic prostatitis, orchitis, seminal vesiculitis, posterior urethritis, and infection of Tyson's and Cowper's glands.<sup>24</sup>

The patient's sexual practice may be a major indication of the potential site of infection. In homosexual males, the rectum is the only site of gonococcal infection in 40% of reported cases. Rectal infection occurs through direct inoculation by receptive anal intercourse and often results in symptomatic disease.<sup>25,26</sup> Symptoms can be quite mild with only pruritus and painless rectal discharge. Conversely, patients can experience severe rectal pain and bloody, mucopurulent discharge. Diagnosis is best made by anoscopy and culture, since external inspection may reveal few signs of infection. Without treatment the patient can become a chronic, asymptomatic carrier. Pharyngeal infection occurs in up to 25% of homosexual men and 7% of heterosexual men who engage in oral-genital contact with an infected partner. Over 90% of pharyngeal infections are asymptomatic but can produce an exudative pharyngitis or tonsillitis. The pharynx is the only site of infection in 5% of patients with gonococcal infection. Pharyngeal infection clears spontaneously in nearly all cases within 12 weeks of infection.<sup>27–30</sup>

### Gonococcal Infection in Women

The clinical presentation of gonorrhea in women is varied, and about 50% of women with endocervical infection are asymptomatic. Although the columnar epithelial cells of the endocervix are the initial site of infection, up to 30% of women with untreated infection develop upper reproductive tract infection or PID.<sup>31,32</sup> In the presence of endocervical infection, infection usually also involves the urethra.

The incubation period for gonorrhea is longer in women than in men but is usually less than 10 days. The clinical presentation is highly variable and includes vaginal discharge secondary to mucopurulent cervicitis (MPC), abnormal menstrual bleeding, and anorectal discomfort.<sup>25,32</sup> Dysuria is also a common symptom of gonococcal infection in women. It is often mistaken for acute bacterial cystitis and should be suspected in young, sexually active women with pyuria in the absence of bacteria. Women who present with dysuria should have a pelvic examination as well as examination of the urethra for inflammatory exudate, and visualization of the cervix for signs of endocervical involvement and specimen collection.

## PATHOGENESIS AND IMMUNITY

Infection with *N. gonorrhoeae* encompasses several specific stages. These include (1) attachment, (2) local proliferation with subsequent colonization of the mucosal cell surface, (3) penetration or invasion, and (4) local inflammatory response or dissemination.<sup>4</sup> Most, if not all, of these stages involve cell surface components that may be subject to phase or antigenic variations. Phase variation refers to the ability of the organism to turn the expression of a gene on or off. In the case of one such gene, gonococcal pilin, the gonococcus has a pilin expression locus, *pilE*, and multiple, silent pilin incomplete variant copies, *pilS*.<sup>33</sup> Gene conversion occurs with the movement of a sequence from a *pilS* locus into the *pilE* expression locus. Incorporation of a *pilS* sequence that alters the structure of the pili results in antigenic variation, but if incorporation of the sequence blocks transcription of or expression of functional pili, phase variation occurs.

We use pilin as an example of this process. Several other outer membrane structures also undergo phase variation, antigenic variation, or both. These include Opa (opacity-related protein), LOS (lipo-oligosaccharide), and PilC (a pilus-associated attachment protein).<sup>34–38</sup>

### Attachment

Following introduction of gonococci onto a mucosal site, gonococci attach to the surface of columnar epithelial cells. Initial attachment is mediated by pili—filamentous, outer membrane appendages composed of multiple subunits.<sup>39</sup> Human challenge studies suggest pili are important for infection, since Pil-negative variants are noninfectious.<sup>40</sup> In addition, these studies demonstrated that multiple pilin variants can be present in a single infection.<sup>41,42</sup> Little is known about the precise mechanism of pilin-associated adherence to epithelial cells, although a putative host cell receptor was identified as CD46, or membrane cofactor protein.<sup>43</sup> Antibodies raised against pili have been shown to block attachment of gonococci to epithelial cells.<sup>33</sup> Subsequent studies have demonstrated that protective pilin antibodies have been directed at the highly variable

pilin epitopes. This may explain why there is such a high degree of pilin antigenic variation by gonococci *in vivo*, since it allows evasion of the first line of host immunity.

Attachment by pili may be further influenced by the PilC proteins: PilC1 and PilC2 are proteins that copurify with pilin and also undergo phase variation.<sup>44</sup> They play a key role in epithelial cell adherence, but there is uncertainty about how they interact with pilin, or how they assist with cell attachment.<sup>45</sup> Gonococcal attachment and invasion are associated with actin rearrangements, membrane ruffling, pedestal formation, and recruitment of phosphorylated host cell proteins and receptors.<sup>46</sup>

Two other outer membrane structures, Opa and gonococcal LOS, are also involved in attachment and invasion of the host cell. The interaction of gonococcal LOS to the human asialoglycoprotein receptor (ASGP-R) allows entry into primary human urethral epithelial cells.<sup>47</sup> Opa proteins are a family of 11 or 12 related proteins that increase the colonial opacity of gonorrhea when viewed under a dissecting microscope.<sup>42</sup> Opa proteins undergo frequent phase and antigenic variation, with up to four or five different Opa genes being simultaneously expressed with a change in frequency of about 0.001 per cell per generation.<sup>48</sup>

Opa antigenic variation is regulated by translational frame shifting, which is due to a high-frequency, spontaneous variation in the number of CTCTT oligonucleotide repeats in the signal encoding sequence of the Opa region.<sup>38</sup> Each Opa contains two hypervariable regions (HV-1 and HV-2), which are surface-exposed and promote the intimate attachment of gonococci to the host cell.<sup>49,50</sup> Experimental infection in the urethra of male volunteers suggests the need for Opa phenotypic expression for infection to occur.<sup>51,52</sup> In addition, Opa is necessary for endocytosis by eukaryotic cells.<sup>53</sup> Antibodies directed against these regions decrease cell adherence, but no cross-reacting Opa antibodies have been found to block adherence. Several studies suggest that only a few Opa types may be able to mediate cellular attachment or induce endocytosis.<sup>53</sup> Opa binding sites that have been identified include heparin sulfate proteoglycans and carcinoembryonic antigen-like cell adhesion molecules (CEACAMs, formerly referred to as CD66 antigens).<sup>54,55</sup> Expression of different members of the CEACAMs family may explain preferential binding of gonococci to particular cells, since various Opa variants exhibit different binding specificities for various CEACAMs family members.<sup>56</sup>

CEACAM engagement on professional phagocytic cells results in the activation of the host cell Src tyrosine kinases, Hck and Fgr, which is then followed by Rac activation. Rac activation, in turn, triggers cytoskeletal rearrangement and internalization of the gonococcus.<sup>57</sup>

Although Opa is important in the pathogenesis of gonococcal infection, gonococcal isolates from the upper genital tract of women are less likely to express Opa than isolates from the lower genital tract.<sup>58</sup> It is possible that the initial lower tract infection involves Opa but the subsequent production of antibodies directed against Opa exerts pressure for the selection of gonococcal strains that do not express Opa. These Opa-negative strains then ascend the genital tract (by means other than transcellular migration) to cause upper tract infection. Antibodies directed against Opa may have protective benefits in women with gonococcal infection, since the presence of antibodies to increasing number of Opa variants was correlated with a lower risk of developing salpingitis after an episode of cervical infection.<sup>59</sup>

This antibody response does not result in protection from acquisition of gonococcal infection. The role of Opa in the pathogenesis of infection is the subject of study in several laboratories.

Gonococci express a heterogeneous mixture of LOS in their outer membrane. The LOS of *N. gonorrhoeae* differs from that of other gram-negative bacteria by the absence of the O-antigenic side chains but possesses similar core oligosaccharide and lipid A.<sup>60</sup> LOS mediates bacterium-bacterium adherence and plays a role in epithelial cell invasion. LOS is known to produce a marked inflammatory response, which is responsible for many of the signs and symptoms associated with gonococcal infection. It causes inflammation by inducing complement activation, lysis of host cells, and the local production of tumor necrosis factor (TNF). These mechanisms cause much of the tissue damage associated with upper tract disease. The exuberant host immune response to gonococcal infection, while leading to control of infection, can account for many of the signs and symptoms of disease. Gonococci are able to escape host defense mechanisms directed against LOS by at least three different means: (1) mimicking the host glycolipids, (2) phase and antigenic variation, and (3) sialylation of the terminal core sugar, which results in masking of LOS.<sup>60</sup> This inhibits antibody recognition of LOS and prevents effective formation and deposition of the terminal complement complex on the gonococcal outer membrane. The presence of sialic acid on gonococcal LOS confers serum resistance but also inhibits Opa-mediated entry into some cells.<sup>61,62</sup> In summary, Por, Opa, and LOS each have individual profound effects on bacterial trafficking across the human genital tract epithelial barrier and influence the effects of one another when they are expressed in combination.<sup>63</sup>

## Proliferation

*In vivo*, free iron is a limiting nutrient for gonococcal proliferation. The ability of gonococci to acquire iron, either in the form of lactoferrin or transferrin, is required for successful colonization of human genital epithelium.<sup>64</sup>

Free iron is scarce in host mucosal sites primarily because high-affinity iron-binding proteins, human transferrin and lactoferrin, act to bind free iron and reduce its availability.<sup>4</sup> In response to iron deprivation, gonococci produce receptors (Tbp1 and Tbp2) for binding human transferrin and human lactoferrin (LBP-1).<sup>33</sup> On binding of transferrin and lactoferrin to the receptors, iron is released and transported across the periplasmic space to the cytoplasmic membrane via a ferric iron-binding protein and hence into the cytoplasm.

Gonococci are able to undergo intracellular replication, both within phagocytic vacuoles and within columnar epithelial cells. Gonococci grow in both aerobic and anaerobic environments.<sup>65</sup> This adaptive response helps gonococci evade phagocytic attack. By utilizing oxygen, gonococci compete with the oxidative metabolism of phagocytic cells and contribute to the development of an anaerobic environment. Unique proteins expressed under these anaerobic conditions may allow survival and replication within leukocyte phagolysosomes. Survival of gonococci in the vaginal tract appears to be enhanced by one of two multidrug-resistance efflux systems (MtrCDE). The MtrCDE system appears to undergo hormonal regulation, suggesting that the secretory stage of the mammalian reproductive cycle, through the effect of progesterone, may inhibit gonococcal survival *in vivo*.<sup>66</sup>

## Local Invasion

Following attachment to mucosal cells, gonococci become engulfed in a process known as parasite-directed endocytosis. This process appears to be enhanced by the outer membrane protein Por (Proteins IA and IB).<sup>67</sup> Porins are trimeric protein structures that form anion-selective transmembrane channels. There are two structurally related forms: PorA and PorB. Por is expressed constitutively and does not undergo high-frequency phase or antigenic variation. Antigenic variation probably occurs by low-frequency mutations of Por.<sup>68</sup> Purified Por exhibits several functions believed to be important in cellular invasion. One is the ability to insert itself into the host cell membrane and collapse the membrane potential.<sup>66,69</sup> The second is its ability to bind calmodulin. As such, it may be able to induce the endocytosis of gonococci into epithelial cells, blunt the polymorphonuclear (PMN) leukocyte oxidative burst, and block phagolysosomal fusion. Por selectively inhibits PMN granule fusion with plasma membrane to downregulate oxidative metabolism.<sup>70</sup> Por is also a basis for strain serotyping.<sup>71</sup> Normal human serum can kill circulating gonococci through the activation of complement and the deposition of terminal complement complex on the cell surface.<sup>60</sup> Disseminated gonococcal isolates are typically serum-resistant and can induce defective deposition of the terminal complement complex on the outer membrane.<sup>60</sup> PorA appears to be crucial to the development of serum resistance, since most invasive strains express PorA. Both PorA and PorB strains cause local infection, although PorB strains are more common.<sup>72</sup>

## Gonococcal Adaptation to Avoid Host Immunity

In order for *N. gonorrhoeae* to survive, it has developed strategies to avoid host defense mechanisms. Examples of these strategies include antigenic and phase variation of Opa, Pil, and LOS.<sup>33,35,37</sup> Four other mechanisms also play an important role in protection from host attack: (1) masking of gonococcal antigen (sialylation of LOS); (2) mimicry (the similarity of terminal LOS sugars to host glycolipids); (3) release of immunoglobulin A (IgA) 1 protease, which cleaves and thus inactivates mucosal IgA; and (4) blocking antigen.<sup>73</sup> This last strategy involves the blocking of mucosal defenses by the binding of antibodies to a reduction modifiable protein (Rmp). Unlike the antigenic variability associated with Por, Opa, and Pil, Rmp has relative antigenic stability within the species and the genus *Neisseria*.<sup>74–77</sup> Rmp is physically associated with Por on the outer membrane of gonococci and is highly immunogenic for non-complement-fixing antibodies. The antibodies directed against Rmp bind to the Por-Rmp complex and block the effective deposition of complement-fixing anti-Por antibodies.<sup>78</sup> Once bound, antibodies to Rmp increase the deposition of C3 and C9 and redirect terminal complement complex to nonlytic sites.<sup>79–81</sup> The presence of anti-Rmp antibodies also correlates with an increased risk of gonococcal mucosal infection.<sup>82</sup> Rmp is closely related to the outer membrane protein 3 (OmpA) of *Escherichia coli* and the class 4 protein of meningococcus.<sup>80</sup> It is possible that Rmp antibodies are acquired in the absence of gonococcal infection by colonization of the intestinal tract by *E. coli* or by nasopharyngeal colonization with meningococcus. In essence, gonococci can use the host immune response against other organisms as its way of preventing an effective response to itself.

Sialylation of LOS on gonococci also prevents the binding of bactericidal antibodies and interferes with the deposition of complement by forming a pseudocapsule on gonococci. This provides a partial immunogenic cover to neighboring Por.<sup>73</sup>

## DIAGNOSIS

Cervical or urethral exudate should be examined by Gram's stain and by culture. Mucopurulent cervicitis is defined by the presence of a yellow-green discoloration on a swab after insertion into the endocervix. In the absence of infection, the swab would remain white or be coated by a clear mucoid discharge. Culture or other diagnostic tests should be used to differentiate gonococcal cervicitis from other causes of cervical inflammation such as chlamydia and herpes simplex. The endocervical Gram's stain sensitivity is only 50% and must demonstrate intracellular gram-negative diplococci to discriminate between *N. gonorrhoeae* and other *Neisseria* and gram-negative species that normally inhabit the vagina and cervix.<sup>24</sup> Whenever possible, it is essential to confirm the diagnosis of gonococcal infection through either culture or through direct or amplified genetic probes.

Other local sites of infection in women include gonococcal proctitis, which is found in 35% to 50% of women with cervicitis and is usually asymptomatic. It can be the only site of infection in 5% of women.<sup>32,83</sup> If symptoms are present, they are similar to those shown by men. Although sore throat and pharyngitis in the STD clinic are often associated with a history of fellatio, gonorrhea or other sexually transmitted infections are not usually isolated.<sup>83,84</sup> Most pharyngeal infections are asymptomatic and clear spontaneously. Pharyngeal gonorrhea is found in 10% to 20% of women with endocervical infection,<sup>84</sup> is associated with an apparent increased risk of dissemination, and has been associated with sexual transmission.<sup>27,84</sup>

Local infection of the endocervix extends to the uterus, fallopian tubes, or adjacent structures in about 15% of women.<sup>31,85,86</sup> Factors contributing to upper tract infections include menstruation, use of an intrauterine device (IUD), a history of douching, adolescent age, or previous history of PID. Clinical signs and symptoms of upper tract infection involve some or all of a constellation including lower abdominal pain, dyspareunia, abnormal menstrual bleeding, adnexal and cervical motion tenderness, fever, and other complaints consistent with an intra-abdominal infection. Endocervical Gram's stain may be helpful and yield a presumptive diagnosis by the presence of intracellular gram-negative diplococci, but it is negative in 40% to 60% of women with PID.<sup>24</sup> Therefore, the diagnosis of PID is usually made on clinical grounds and cannot be distinguished from nongonococcal PID. None of the clinical signs and symptoms have both high sensitivity or specificity for PID. Use of three clinical variables—a high erythrocyte sedimentation rate, fever, and adnexal tenderness—correctly classified only 65% of laparoscopically diagnosed PID.<sup>87</sup> Because of the lack of a diagnostic clinical sign or symptom, the differential diagnosis remains broad and includes ectopic pregnancy, urinary tract infection, pyelonephritis, appendicitis, proctocolitis, and endometriosis.

Early diagnosis and treatment are essential to preventing the complications of PID. Infertility is strongly associated with a history of PID and occurs with increasing frequency: in 11% of women who have had one episode, in 23% with two episodes,

and in 75% with three or more episodes of PID. Other sequelae include chronic pelvic pain and ectopic pregnancy.<sup>24,88</sup>

Other urogenital complications from gonorrhea in women include perihepatitis (Fitz-Hugh–Curtis syndrome), which presents as acute right or bilateral upper quadrant tenderness, frequently with signs and symptoms of PID.<sup>89</sup> Infection of Bartholin's gland duct presents with local erythema and pus at the posterior third of the labia majora.

Infection with gonorrhea during pregnancy is similar in clinical presentation to that in nonpregnant women. However, in women with gonococcal infection, there are higher rates of spontaneous abortion, premature rupture of membranes, acute chorioamnionitis, postpartum endometritis, and premature delivery.<sup>90,91</sup> Asymptomatic women may transmit infection throughout the pregnancy and postpartum periods. In particular peripartum transmission to the newborn may result in infection of the conjunctiva, rectum, or respiratory tract.<sup>92</sup> Gonococcal ophthalmia can be prevented by routine screening for endocervical infection during pregnancy and by the prophylactic use of 1% silver nitrate, erythromycin, or tetracycline ophthalmic solution.<sup>93</sup> These agents may not be available in developing countries. A single application of povidone-iodine 2.5% is an inexpensive alternative with a broad spectrum of activity against chlamydia, gonococcus, HIV, and herpes simplex.<sup>94,95</sup> Given the high rates of tetracycline-resistant *N. gonorrhoeae* (TRNG), tetracycline may no longer be adequate as prophylactic therapy.<sup>4</sup>

## Disseminated Disease

DGI is relatively rare, occurring in 0.5% to 3.0% of untreated mucosal infections.<sup>4</sup> The majority of DGI occurs in persons with asymptomatic mucosal infection. This may be partially due to infection by a distinct clone that typically causes minimally symptomatic mucosal infection but is prone to systemic dissemination. This clone exhibits the AHU auxotype, PorIA serovar, and serum-resistant phenotype. Host factors are also important with women, accounting for about 70% of disseminated disease and bacteremia, often beginning during menses. Patients with terminal complement component deficiency are particularly susceptible to systemic infection with the gonococcus and meningococcus.<sup>96</sup>

The clinical manifestations of DGI are a result of gonococcal bacteremia, although patients typically lack the classic signs of bacteremia, that is, high fever, leukocytosis, or systemic toxicity.<sup>4</sup> The most common presentation of DGI is polyarthritides. Gonococcal arthritis can, however, present as monoarticular arthritis, the most common cause of acute arthritis in young adults. An important clinical finding that helps differentiate gonococcal arthritis from other infectious causes is tenosynovitis, which often occurs over the involved joint and is sometimes accompanied by erythema.<sup>97</sup> Skin lesions, which typically occur throughout this period, appear as sparse, pustular lesions with surrounding erythema on the distal extremities. Lesions are present in 50% to 75% of patients but number fewer than 30 in most cases.<sup>98,99</sup>

Purulent arthritis is a later manifestation of the arthritis-dermatitis syndrome associated with DGI and occurs in approximately 30% to 40% of patients with DGI. Synovial fluid cultures are usually sterile but are more frequently positive in patients with synovial fluid leukocyte counts greater

than 40,000/ $\mu$ L.<sup>100</sup> Blood and skin lesion cultures are usually also sterile, with the overall yield of blood cultures being less than 30% but decreasing with the duration of clinical illness.<sup>101</sup> This may be due to the intermittent, low level of bacteremia, the extraordinary nutritional requirements of the gonorrhea strains most likely to disseminate, and the role of immunocomplex deposition as a cause of local inflammation.

Other manifestations of DGI include mild pericarditis, endocarditis, and meningitis (each of which is seen in fewer than 3% of patients with DGI).<sup>100–102</sup>

To confirm the diagnosis of DGI, cultures should be obtained from all mucosal sites. In more than 80% of patients, gonococci can be isolated from genital, rectal, or pharyngeal cultures. In cases in which cultures are negative from all mucosal sites, isolation of *N. gonorrhoeae* from the sexual partners may be the only means of confirming the diagnosis.

## Culture

The gold standard for detection of *N. gonorrhoeae* has been the culture. The widespread use of nucleic acid amplification tests (NAATs) may signify a change in this long-standing standard. The main benefits of culture are high specificity and the ability to do additional studies, such as antimicrobial susceptibility testing on culture isolates. The disadvantages of culture can be substantial in developing countries because of the stringent storage and transport requirements of culture media, the fastidious growth requirements of *N. gonorrhoeae*, and the delay in obtaining results. Test performance, available technology, cost, and prevalence of gonorrhea must be taken into account when selecting diagnostic tests to be used for identifying gonococcal infection. Ideally, the test should be highly sensitive, specific, rapid, and inexpensive.<sup>103</sup>

The yield of gonococcal culture largely depends on the anatomic site of the culture and the use of selective or non-selective media. Selective media contain several antibiotics to prevent the overgrowth of genitourinary, enteric, and oral flora. Modified Thayer-Martin (MTM) is probably the most widely used selective medium, with an overall sensitivity of 80% to 95% for isolation of *N. gonorrhoeae*. Other selective media include NYC (New York City), Martin-Lewis (ML), and GC-Lect. There are significant differences among these media. MTM lacks serum and inhibits the growth of 3% to 10% of *N. gonorrhoeae* strains because of its high concentration of vancomycin (3  $\mu$ g/mL) relative to other media. Additionally, it is difficult to predict when vancomycin-sensitive strains may be present, because of geographic variation in prevalence. Vancomycin-sensitive strains are more likely to be found in heterosexuals, whites, and asymptomatic carriers. Moreover, growth of vancomycin-sensitive strains largely depends on the size of the inoculum; smaller inocula are more likely to be inhibited. GC-Lect medium has some advantage over MTM for the isolation of vancomycin-sensitive strains owing to its lower concentration of vancomycin (2  $\mu$ g/mL) and the presence of supplemental nutrients. NYC medium is serum-enriched and also has a vancomycin concentration of 2  $\mu$ g/mL. NYC medium is translucent and therefore facilitates both the selection of oxidase-positive colonies and viewing under a stereomicroscope. Production variability and increased cost render NYC less useful than MTM.

To prevent the overgrowth of gonococcal colonies with normal flora, it is best to use selective media in sites with a higher concentration of easily cultured bacteria, such as the rectum, pharynx, and endocervix. Nonselective media can be used for urethral specimens from men with symptomatic urethritis because of the high concentration of gonococci relative to that of other genital flora.

In women, a single culture of the endocervix is usually sufficient for isolation of gonococci because infection usually involves the cervix. It is rare to detect infection in other sites without first finding it in the cervix. For women who have undergone a hysterectomy, urethral cultures are indicated. Consideration of culturing the accessory gland ducts, pharynx, and rectum is based on clinical presentation, site of sexual contact, and cost.

### Gram's Stain

Low cost and rapidity of diagnosis make Gram's stain of clinical specimens an important test for the evaluation of gonorrhea in the clinical setting. Gram's stain is considered positive if neutrophils with intracellular gram-negative diplococci are observed. It is considered negative in the absence of gram-negative diplococci, and equivocal following observation of extracellular gram-negative or morphologically atypical-appearing organisms.<sup>103,104</sup> Because it is not possible to distinguish *N. meningitidis* from *N. gonorrhoeae* by Gram's stain, it is sometimes necessary to confirm the diagnosis through culture. Other nonpathogenic *Neisseria* species are usually not present as intracellular organisms.

The sensitivity and specificity of the Gram's stain smear varies, depending on the site of infection and the presence or absence of symptoms. For symptomatic urethritis in men, the high sensitivity and specificity, 95% and 98%, respectively, suffices for diagnosis.<sup>104–107</sup> In asymptomatic males, the sensitivity is significantly lower and requires a culture to rule out gonococcal infection. Lower sensitivity (40% to 60%) is also seen in Gram's stains of endocervical samples from symptomatic women, although it retains a high specificity in these cases. Owing to high specificity, it is possible to make a presumptive diagnosis on the basis of a positive smear. The high intraobserver variability in preparing and reading endocervical Gram's stains renders unreliable the reading of a negative Gram's stain.<sup>103,106</sup> Although sometimes useful, the Gram-stained smear of the rectum, pharynx, and other sites should be used only in conjunction with cultures or other diagnostic tests to confirm diagnosis.

### Nucleic Acid Amplification Tests

NAAT methodology involves amplification of specific *N. gonorrhoeae* DNA or RNA sequences by polymerase chain reaction (PCR), strand displacement assay (SDA), or transcription-mediated assay (TMA). Commercially available ligase chain reaction (LCR) is no longer available. NAATs have reported sensitivities and specificities from urethral and endocervical specimens that are comparable to culture.<sup>108,109</sup> The advantages of these tests over culture are the rapidity of results and the high sensitivity compared with culture. The latter has allowed testing for *N. gonorrhoeae* by NAATs to be applied to urine specimens and vaginal swabs.<sup>110</sup> Urine-based

testing permits screening of populations outside the traditional clinic setting and identification of the asymptomatic carrier of *N. gonorrhoeae* without invasive testing. First-generation NAATs had difficulties with cross-reactivity with nongonococcal *Neisseria* species. Second-generation NAATs approach zero cross-reactivity with nongonococcal species and have the added advantage of being able to simultaneously identify *N. gonorrhoeae* and *Chlamydia trachomatis*. Studies with TMA have demonstrated excellent performance diagnosing anorectal or pharyngeal infection.<sup>111</sup>

The high sensitivity of NAATs has a trade-off in that specificity is not 100%. There can be false-positive results when screening is performed in low-prevalence populations.<sup>112</sup> Caution must be given to use of NAATs in screening asymptomatic populations. Even with reported high specificity, there is reason to be concerned that a poor positive predictive value with vaginal swabs may occur with PCR and could still be an issue for TMA and SDA.<sup>113</sup>

### Other Diagnostic Tests

Specimen collection, transportation, and storage issues all contribute to failure in culture identification of gonococcal infection.<sup>114</sup> With the development of nonculture diagnostic tests, it is increasingly possible to confirm the diagnosis through other methods: enzyme immunoassays, DNA probes, and DNA amplification assays.<sup>108,115,116</sup> These diagnostic methods potentially offer more rapid results and higher sensitivity than culture. DNA probe assays for gonorrhea have a reported sensitivity of 93% to 99% and specificity of 98% to 99.5%.<sup>117</sup> One DNA probe, PACE 2, combines probes against *N. gonorrhoeae* and *C. trachomatis* into a single test with sensitivity and specificity comparable to the single probe for *N. gonorrhoeae*.<sup>118</sup> In addition, not all nonculture tests produce gonococcal isolates that may be used for antimicrobial susceptibility testing. For this reason, it is best that they not replace the use of ongoing surveillance systems. In the future, commercially available NAATs may identify resistance genes. Correlation of genetic markers of resistance to clinical isolates will still need to be made prior to widespread use of this technology as part of resistance monitoring.

## TREATMENT

### Antimicrobial Resistance

Control of gonococcal disease has depended heavily on the use of highly effective and preferably single-dose antibiotic therapy.<sup>118</sup> As early as the 1950s, however, reduced susceptibility to penicillin was reported.<sup>119</sup> Unfortunately, antimicrobial resistance has continued to evolve and spread since that time. Antibiotic resistance remains disproportionately represented in less developed nations and in socially marginalized groups. The reasons for the development of resistance are complex but can be attributed to four major factors: (1) poor compliance with prescribed therapy, (2) inadequate dosing of antibiotics, (3) circumstances causing low or inadequate antibiotic serum levels, and (4) conditions favoring the selection of resistance mutations (such as the widespread use of antimicrobial agents in the general population).

Antibiotic resistance occurs through two main mechanisms: chromosomal and plasmid-mediated resistance. Chromosomal

resistance is encoded at several different loci and usually occurs as a stepwise, incremental resistance pattern. The single exception to stepwise chromosomal resistance is spectinomycin, to which high-level resistance occurs after a single alteration to the ribosomal target.<sup>120,121</sup> Plasmid resistance usually occurs as a one-step change to high-level resistance and rapidly spreads through a population.

Therapeutic regimens should be based on the knowledge of the in vitro sensitivity of prevalent gonococci in the immediate region. A strong argument can be made that regional susceptibility patterns are more important than strain susceptibility in a given individual.<sup>122</sup> This is especially important because most treatment occurs prior to obtaining the antimicrobial susceptibilities on a particular gonococcal isolate. Increasing minimum inhibitory concentrations (MICs) to antimicrobial therapy partially explains the rise in treatment failure, which further highlights the importance of monitoring resistance patterns in order to accurately select treatment regimens. In turn, this can further the discovery of new resistance patterns as they develop. Ideally, this monitoring should be a continuous surveillance program. Owing to financial constraints, point prevalence studies at repeated intervals can be performed to follow temporal changes in susceptibility patterns.

The specific incidence of antibiotic resistance is geographically variable, but effective treatment is a common challenge in several countries. In the United States, the Far East, and western and central Africa,<sup>123</sup> treatment with penicillin and tetracycline is unreliable owing to the appearance in gonococci of plasmids that produce  $\beta$ -lactamase, resulting in penicillinase-producing *N. gonorrhoeae* (PPNG); of plasmids that mediate high-level TRNG; and emergence over many decades of chromosomally mediated penicillin- and tetracycline-resistant *N. gonorrhoeae* (CMRNG).<sup>123–125</sup> PPNG strains are characterized by the production of  $\beta$ -lactamase and have MICs for penicillin greater than or equal to 16  $\mu\text{g/mL}$ . CMRNG strains are characterized by the lack of  $\beta$ -lactamase production and have penicillin MICs less than 8  $\mu\text{g/mL}$ . A strain can have plasmid-mediated resistance to both penicillin and tetracycline (PPNG-TRNG). Chromosomal-resistant strains usually have MICs less than or equal to 2  $\mu\text{g/mL}$  for tetracycline, penicillin, or cefoxitin. In general, chromosomal resistance occurs through alterations in antimicrobial-binding proteins or through decreased net permeability of the gonococcal outer membrane.<sup>119,126</sup>

In reaction to widespread penicillin and tetracycline resistance, the Centers for Disease Control and Prevention (CDC) in 1987 ceased to recommend the first-line use of these agents for treatment of gonorrhea. It then began advocating the use of third-generation cephalosporins and selected fluoroquinolones.<sup>127,128</sup> Fortunately, ceftriaxone continues to be effective with no reported resistance. Cefixime had been the only oral cephalosporin recommended by the CDC for the treatment of uncomplicated gonococcal infection. The sole company manufacturing cefixime ceased manufacturing it in the United States in July 2002, and the drug is no longer available in the United States.<sup>129</sup>

Cefpodoxime has recently been advocated as a replacement for cefixime.<sup>130</sup> There is some concern, however, regarding the potential emergence of strains resistant to the use of a 200-mg dose of cefpodoxime and a similar concern of emerging resistance to cefixime should it again become widely available. The clinical data for cefpodoxime are sparse, at best, with only one

clinical trial reported in the literature. Although it appears cefpodoxime therapy at 200 mg and 400 mg is equivalent, only two patients were treated with the 200-mg dose.<sup>131</sup> Monitoring for the emergence of resistance or evidence of clinical treatment failure is recommended for areas where cefpodoxime is used as first-line treatment for uncomplicated gonococcal infection.

The concern over potential cefixime resistance stems from application of a therapeutic index, defined by the ratio of peak serum concentration to MIC. The recommended therapeutic index is a ratio greater than 3 to 4:1, as determined by the use of penicillin G for the treatment of gonococcal urethritis.<sup>132</sup> Antimicrobial agents with a therapeutic index greater than 4 are highly effective in curing gonorrhea. Relative to other therapies, cefixime demonstrates a low peak serum level. The recommended dose of cefixime, 400 mg PO, produces a peak serum level of 4  $\mu\text{g/mL}$ , while 500 mg of ceftriaxone IM produces peak serum concentrations of 42 to 45  $\mu\text{g/mL}$ . This concentration is more than 1000 times greater than the MIC for *N. gonorrhoeae*.<sup>133,134</sup>

Of greater concern is the emergence of fluoroquinolone resistance (QNRG), which has been noted in the Far East, Australia, Africa, Europe, and (most recently) the United States.<sup>135</sup> Fluoroquinolone resistance is chromosomally mediated and affects all members of this class of drug. Ciprofloxacin is decreasing in effectiveness in most areas of the United States and Africa. QNRG is endemic in Hawaii and California with increases in QNRG seen in Washington state and Massachusetts. Widespread increases in QNRG have been noted in MSM throughout the United States. This prompted the CDC to issue behavior-specific recommendations on treatment of gonorrhea. Because prevalence does not appear to be high among heterosexuals, broad-based changes have not been made for heterosexuals. Concern does arise for the willingness of men to identify MSM activity in areas where the stigma of homosexuality remains high. As a result, it may be prudent to have gender-specific recommendations for treatment where the prevalence for QNRG remains high for MSM. The trend in increasing prevalence of QNRG warrants close surveillance and adherence to several recommendations regarding the use of fluoroquinolones for gonorrhea:

1. Avoiding use of fluoroquinolones to treat gonorrhea in natives of, or travelers from, Asia or the western Pacific countries, Hawaii, or California (owing to prevalence of high-level resistance)
2. Avoiding use of fluoroquinolones to treat gonorrhea in MSM. Consideration should be given to avoid use of fluoroquinolones in all men and women with gonorrhea where QNRG in MSM is a concern, since men may not disclose MSM activity and women have a high rate of asymptomatic infection with *N. gonorrhoeae*
3. Using only the recommended doses of fluoroquinolones (500 mg of ciprofloxacin or 400 mg of ofloxacin when they are used for treatment of gonorrhea)
4. Prescribing single-dose therapy with the additional use of azithromycin or doxycycline, which may retard the selection of resistance

### Antimicrobial Therapy

Ideally, antimicrobial therapy for gonorrhea should be safe, be inexpensive, and achieve rapid serum and tissue

levels at least three to four times greater than the MIC of the infecting gonococcal strain. Treatment regimens for uncomplicated gonorrhea should cure at least 95% of infections by a single dose of therapy. In 2002, the CDC recommended two fluoroquinolones—oral ciprofloxacin 500 mg and oral ofloxacin 400 mg—or two broad-spectrum cephalosporins—oral cefixime 400 mg or IM ceftriaxone 125 mg—for the treatment of uncomplicated gonorrhea.<sup>136</sup> The continued evolution of gonococcal resistance has led to significant changes to the 2002 recommendations. The ideal therapeutic index (ratio of peak serum concentration to MIC of 3 to 4:1) is achieved with the recommended regimens of cefixime or ceftriaxone. Ciprofloxacin achieves peak serum concentrations of 2.5 µg/mL following a single 500-mg oral dose and should be adequate for treating gonococcal strains with decreased susceptibilities (MIC of 0.125 to 0.5 µg/mL). Ciprofloxacin-resistant strains are defined as having an MIC greater than 1.0 µg/mL and nonresponsive to the recommended dose.<sup>124</sup> Ceftriaxone, cefixime, and ciprofloxacin all clear *N. gonorrhoeae* in less than 24 hours from the urethral mucosa and semen of men.<sup>137</sup> Because of the rapid clearance of infection and the high potency of the recommended treatment regimens, test of cure is not indicated following treatment for uncomplicated gonorrhea with current cephalosporin regimens. The high rate of coinfection with chlamydia in most geographic areas—15% to 20% among men and 30% to 50% among women—necessitates empirical treatment of chlamydia infection with all gonorrhea treatment regimens.<sup>138,139</sup> Current recommendations in the United States call for either ceftriaxone 125 mg IM or cefixime 400 mg PO (not currently available in the United States) or spectinomycin 2.0 g IM plus treatment for possible coinfection with *C. trachomatis* with either single-dose azithromycin 1.0 g PO, or with doxycycline 100 mg PO two times per day for 7 days.<sup>139,140</sup> Ciprofloxacin and ofloxacin are contraindicated in pregnant and nursing women, and relatively contraindicated in children less than 18 years of age. Persons who may have acquired gonorrhea in Asia, the Pacific Rim (including Hawaii), California, and other areas such as England and Wales with high rates of QNRG should not be treated with fluoroquinolones.<sup>141</sup> The CDC has now added MSM as a group for whom alternatives to fluoroquinolones should be used for the treatment of gonorrhea. An additional consideration for choice of therapy given the recent increase in syphilis in MSM is that ciprofloxacin and ofloxacin are not active against *Treponema pallidum* and are therefore not effective against incubating syphilis. Consideration should be given to using a regimen containing ceftriaxone or azithromycin where syphilis prevalence remains high.<sup>142</sup>

Alternative regimens for those unable to take cephalosporins or quinolones include spectinomycin 2 g IM, kanamycin 2 g IM, or gentamicin 240 mg IM.<sup>136,143,144</sup> Because of the low risk of cross-reactions between penicillin and cephalosporins with single-dose therapy, cephalosporins may be used in patients with penicillin allergies, unless there is a history of an immediate IgE-mediated hypersensitivity reaction.

Pharyngeal gonococcal infection may be treated with ceftriaxone 125 mg IM. An alternative regimen for those unable to be treated with cephalosporins is ciprofloxacin 500 mg or ofloxacin 400 mg PO.<sup>136</sup> When considering alternative regimens, it is important to note that spectinomycin is ineffective

against pharyngeal infection.<sup>143</sup> Its use in the United States has been limited to pregnant women who are unable to take cephalosporins.

Gonorrhea in pregnancy is best treated with ceftriaxone 250 mg IM, plus a regimen active against *C. trachomatis* with erythromycin base 500 mg PO, four times a day for 7 days, or amoxicillin 500 mg PO three times a day for 7 days, or azithromycin 1.0 g PO.<sup>136,143</sup> Pregnant women for whom cephalosporins are contraindicated may be treated with spectinomycin 2 g IM once. Pregnant women should have rectal and endocervical cultures for *N. gonorrhoeae* obtained 3 to 7 days following therapy as a test of cure.

DGI requires hospitalization for observation of response to therapy and to assure compliance. The recommended initial regimen for DGI is ceftriaxone 1 g IM or IV every 24 hours.<sup>136,143</sup> If patients are allergic to cephalosporins, therapy should include spectinomycin 2 g IM every 12 hours.<sup>136</sup> Resolution of symptoms usually occurs within 24 to 48 hours of initiation of therapy. In patients with a prompt clinical response to therapy and whose compliance is likely, therapy can be completed on an outpatient basis, with an oral regimen of cefixime 400 mg twice per day or cefpodoxime 400 mg twice per day, or (if QNRG is not a consideration) ciprofloxacin 500 mg twice per day or ofloxacin 400 mg twice per day to complete 7 to 10 days of total antibiotic therapy.<sup>136</sup>

Meningitis and endocarditis require high-dose intravenous therapy with a highly active agent that achieves adequate tissue levels in the site of infection, such as ceftriaxone 1 to 2 g IV every 12 hours. The duration of therapy should be a minimum of 10 to 14 days for gonococcal meningitis and a minimum of 4 weeks for gonococcal endocarditis.<sup>136</sup>

PID requires prompt treatment to reduce the incidence of chronic infection, chronic pelvic pain, and infertility. Women must be evaluated to distinguish PID from appendicitis and ectopic pregnancy. Severely ill women—those with high fever, severe pain, or inability to tolerate oral fluids—should be treated in the hospital until they are afebrile and have clinically improved. Outpatient therapy is best limited to nonpregnant, compliant women with mild-to-moderate disease. Follow-up examination is performed within 48 to 72 hours to monitor for clinical improvement in signs and symptoms. The two main therapeutic options appear in Table 26-1.

## PREVENTION AND CONTROL

Despite widely available effective therapy, the persistence of gonorrhea at epidemic levels demonstrates the failure of current control programs. Persistence of STDs in a community can be described by the equation<sup>145</sup>

$$Ro = BcD$$

Where Ro (the reproductive rate) is greater than 1, the disease will increase in prevalence in the community. The reproductive rate is dependent on the efficiency of transmission (B), the rate of sexual partner change (c), and the duration of infectiousness (D). Attempts to reduce the reproductive rate can be directed at interventions that may alter these factors.

Barrier methods remain one of the most effective means of reducing the transmission of gonorrhea.<sup>146</sup> For men, this

**Table 26-1 Therapy for Pelvic Inflammatory Disease in Women**

Outpatient Therapy	Inpatient Therapy*
Option A Ceftriaxone 250 mg IM <i>or</i> Cefoxitin 2.0 g IM with probenecid 1.0 g PO <i>plus</i> Doxycycline 100 mg PO, twice per day for 14 days	Option A Cefoxitin 2.0 g IV every 6 hours <i>or</i> Cefotetan 2.0 g IV every 12 hours <i>plus</i> Doxycycline 100 mg IV every 12 hours
Option B Ofloxacin 400 mg PO, twice per day for 14 days <i>plus</i> Metronidazole 500 mg PO, twice per day for 14 days	Option B Clindamycin 900 mg IV every 8 hours <i>plus</i> Gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) every 8 hours

\*IV therapy should be continued for a minimum of 48 hours after clinical improvement and, once the patient is switched to oral therapy, completed with doxycycline 100 mg PO twice per day for a total of 14 days of antimicrobial therapy.<sup>9</sup>

includes the use of latex or polyurethane condoms. The current version of the female polyurethane condom has been demonstrated to reduce the transmission of trichomoniasis, but studies evaluating its effectiveness in reducing the transmission of gonorrhea have not been published.<sup>147</sup> The major drawbacks to all barrier methods are noncompliance and unacceptability. The female condom presents identical problems. These issues are further complicated by male resistance to the use of the female condom.

Methods which allow more autonomy in initiation by females include the use of vaginal microbicidal agents. When used intravaginally, the currently available agent, nonoxynol-9, reduces the risk of gonorrhea by 10% to 70%.<sup>148</sup> Since nonoxynol-9 is a detergent that can disrupt the lipid bilayers of cell membranes, it can cause mucosal irritation and ulcers and thus increase the risk of HIV transmission. As a result, nonoxynol-9 as means of gonorrhea prevention is no longer recommended.

Vaccines offer the hope of reducing the efficiency of transmission. Crude killed, whole-cell vaccines have been tried in humans and primates, but they are likely to be more toxic than subunit vaccines and offered no protection in human trials.<sup>149</sup> To date, subunit vaccines directed against Pil and Por have not prevented infection in human volunteers.<sup>150,151</sup> Future vaccines may target PilC, TbpB (an immunogenic component of the transferrin receptor), or FrpB (a partially conserved outer membrane iron-repressed protein).<sup>60</sup> DNA vaccines offer a highly promising approach to effective immunogenic response but have yet to be studied for a gonococcal vaccine. A recent study using a DNA vaccine for priming an antibody response to PorB resulted in a high titer and long-lasting antibody response in an animal model.<sup>152</sup>

Until the availability of an effective vaccine, behavioral intervention remains a crucial strategy for reducing the spread of gonorrhea. Behavioral intervention aims to increase condom use/acceptability and to both delay sexual debut and reduce the rate of partner change. Transmission of gonorrhea is further influenced by factors that affect health-care utilization. The essential components of an effective control program are providing increased access to health care, providing the opportunity for treatment at the earliest presentation of symptoms,

identifying high-risk groups for targeted interventions, screening high-risk asymptomatic patients for infection, identifying and treating sexual partners of patients with gonorrhea, and rescreening those identified with infection 3 to 4 months after treatment.<sup>136</sup>

## Haemophilus ducreyi Infections

ALLAN RONALD

*Haemophilus ducreyi* (really an *Actinobacillus*) is a leading cause (along with syphilis and herpes simplex virus) of genital ulcers. Most prevalent in tropical developing areas, it likely predisposes to increased HIV acquisition and is an important target of sexually transmitted disease (STD) control programs.

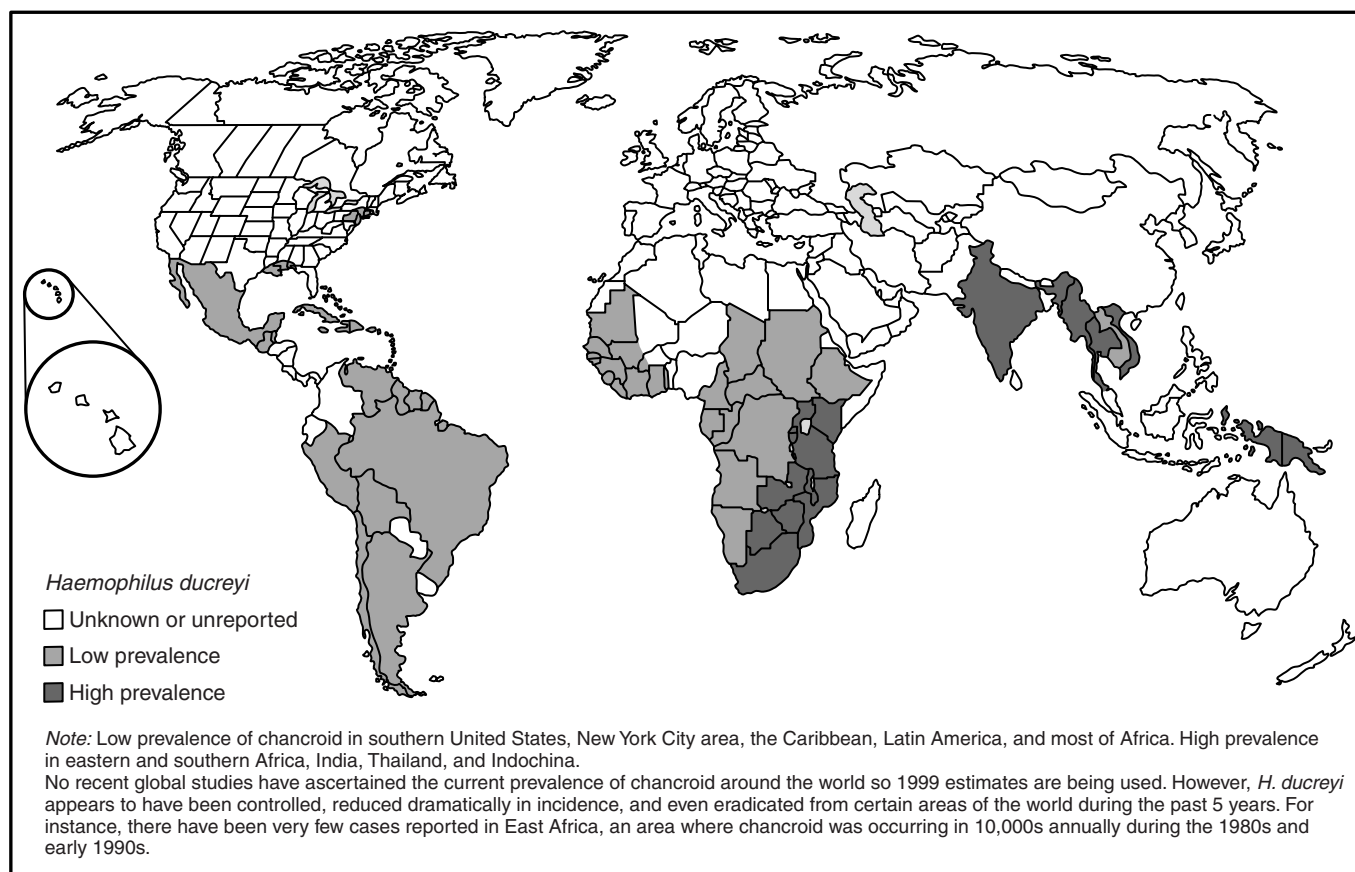

### AGENT

The organism *H. ducreyi* no longer is classified taxonomically by 16S rRNA within the *Haemophilus* genus but rather

is more properly cited within the *Actinobacillus* cluster.<sup>1</sup> The organisms stain faintly with Gram's stain and are arranged in "school of fish" or "railway tracks" patterns. *H. ducreyi* is fastidious and grows best on media supplemented with vitamins, vancomycin to inhibit growth of gram-positive organisms, and charcoal to absorb toxic substances.<sup>2</sup> *H. ducreyi* has a capsule, pili, and several virulence factors.<sup>3</sup>

### EPIDEMIOLOGY

*H. ducreyi* is spread only through sexual transmission. The organism has no known reservoir other than persons with ulcers that may not be clinically obvious and does not preclude individuals, particularly female sex workers, from transmitting it. The annual global incidence of chancroid has been reduced dramatically in the past decade and is now probably below 2 million. More than 99% of cases occur in developing countries, particularly southern Africa and India. Following exposure, uncircumcised men are three times more susceptible to infection. Among female sex workers in developing countries in the 1980s, as many as 10% had ulcers and were transmitting *H. ducreyi*.<sup>4</sup> *H. ducreyi* is readily transmitted between heterosexual partners during unprotected intercourse, with a risk of infection that exceeds 50%.<sup>4</sup> Chancroid also enhances the probability of HIV transmission. *H. ducreyi* ulceration recruits lymphocytes and macrophages to the mucosal surface and provides an easy target of entry for HIV from the genital secretions of the sexual partner.<sup>5</sup> HIV-infected

persons who acquire chancroid excrete the virus in the ulcer and expose subsequent sexual partners to a substantive risk of infection. In some societies, the contribution of chancroid to the HIV epidemic may be as much as one-quarter of the total incidence of HIV infection.<sup>6</sup>

## DISEASE

Chancroid is an ulcerating disease characterized by multiple shaggy undermining lesions on the genitalia. *H. ducreyi* does not cause systemic, invasive infection. The ulcers are usually painful, often quite superficial, and in about 40% of patients, associated with inguinal lymphadenitis. If untreated, the adenitis proceeds to bubo formation and may drain spontaneously, creating an inguinal abscess. In men, about half the ulcers occur on the prepuce and the rest on the glans, in the urethra, on the penile shaft, and on the scrotum and adjacent skin. Kissing lesions are common. In women the lesions occur commonly at the vestibular entrance, particularly on the posterior fourchette. However, numerous lesions are frequently widely present on the inner aspects of the labia majora and on the labia minora. Women with chancroid have a median of four ulcers.

Despite the apparent classic features of chancroid, numerous studies have shown that clinical etiologic identification and differentiation from syphilis, genital herpes, and granuloma inguinale is not possible.<sup>7</sup> As a result, syndromic management to include chancroid is essential for all patients with genital ulcer disease (GUD) if chancroid is endemic in the region.

## PATHOGENESIS

*H. ducreyi* has cytotoxic and hemolytic proteins that are important determinants of virulence in both animal models and in human volunteer studies.<sup>3</sup> Attachment and invasion of epithelial cells are also necessary for virulence. The host response is predominantly mononuclear with a preponderance of activated T lymphocytes and macrophages.

## DIAGNOSIS

*H. ducreyi* can be transported in supplemented thioglycolate transport media and kept for up to 24 hours at 4°C. However, ideally the culture should be plated immediately onto specially prepared chocolate media.<sup>2</sup> Growth is optimal at 32°C in a CO<sub>2</sub> environment with 100% humidity. A candle jar with a moistened paper towel provides a satisfactory environment. Growth often is not apparent before 48 hours. The opaque yellow-gray colony can usually be moved intact across the agar surface. Biochemical studies have limited use. Polymerase chain reaction (PCR) technology has been adapted to identify *H. ducreyi* from genital ulcer specimens and, when combined with PCR primers and probes for

*Treponema pallidum* and herpes simplex virus, can identify the cause of GUD in most patients. Serologic tests for chancroid are neither specific nor sensitive.

## TREATMENT

Chancroid can be effectively treated with erythromycin and with the fluoroquinolones. Most strains are resistant to ampicillin, tetracycline, and sulfonamides. Erythromycin is prescribed for 7 days in a dose of 500 mg three times a day.<sup>8</sup> Ciprofloxacin can be prescribed as a single daily dose of 500 mg.<sup>8</sup> Both regimens have cure rates in excess of 90%. Inguinal buboes should be incised or aspirated if they become fluctuant.

## PREVENTION

Chancroid prevention requires implementation of conventional STD control initiatives. Primary prevention strategies include promotion of safer sex, widespread use of condoms, and partner referral with empiric treatment of contacts. Efforts to encourage early diagnosis through self-referral and appropriate syndromic treatment at the first point of contact with the health system are also important strategies. Routine examination of sex workers with empirical treatment of genital ulceration with regimens effective against chancroid and syphilis reduces the reservoir of this pathogen and rapidly reduces the incidence of chancroid. No vaccine is currently available. However, STD control measures are effective, even in resource-limited societies, and should be a high priority within the health-care system.

# Haemophilus influenzae (Including *H. aegyptius*) Infection

MARK C. STEINHOFF  
THOMAS CHERIAN

## INTRODUCTION

*Haemophilus influenzae* is among the most common causes of bacterial meningitis and other invasive infections in infants and young children throughout the world. Historically in the developing world, it has not been recognized as a vaccine-preventable cause of serious morbidity, long-term disability, and death. The availability of an effective vaccine against *H. influenzae* type b (Hib), which can virtually eliminate Hib disease, underscores the importance of determining the burden of vaccine-preventable illness caused by Hib. It also deserves recognition as a tropical illness in view of its global swath of illness and death.<sup>1</sup>

The related *Haemophilus aegyptius* is responsible for epidemic acute purulent conjunctivitis. This infection is more common in the developing world, for reasons that are not well understood. The epidemics of purpuric fever in Brazil caused by a strain of *H. aegyptius* are not a recent problem, and similar epidemics have not occurred elsewhere.

## AGENTS

E Pfeiffer in 1889 first described the “influenza bacillus” in Germany during an influenza epidemic, mistakenly reporting it as the cause of influenza. The genus *Haemophilus* (“blood-loving” in Greek) was formally named in 1920, to mark its requirement for blood substances in artificial media.

*H. influenzae* is a small, fastidious gram-negative bacterium that requires hemin (X factor) and nicotinamide adenine dinucleotide (NAD, or V factor) for growth on artificial media. NAD is not available in routine blood agar, which accounts for its apparent absence in laboratories that do not use chocolate agar (made by heating blood so that red blood cells lyse and release V factor), or supplemented media such as Fildes or Leventhal agar. The organism elaborates a polysaccharide capsule that permits classification into six distinct capsular serotypes (a through f). The capsular subtype b (Hib) has caused over 90% of all invasive infections. In addition, *H. influenzae*

can be biochemically typed into six biotypes (I through VI). The biotypes and the capsular serotypes are distinct typing methods, not correlated with each other. The entire Hib chromosome was sequenced in 1995, the first free-living organism to be DNA sequenced.

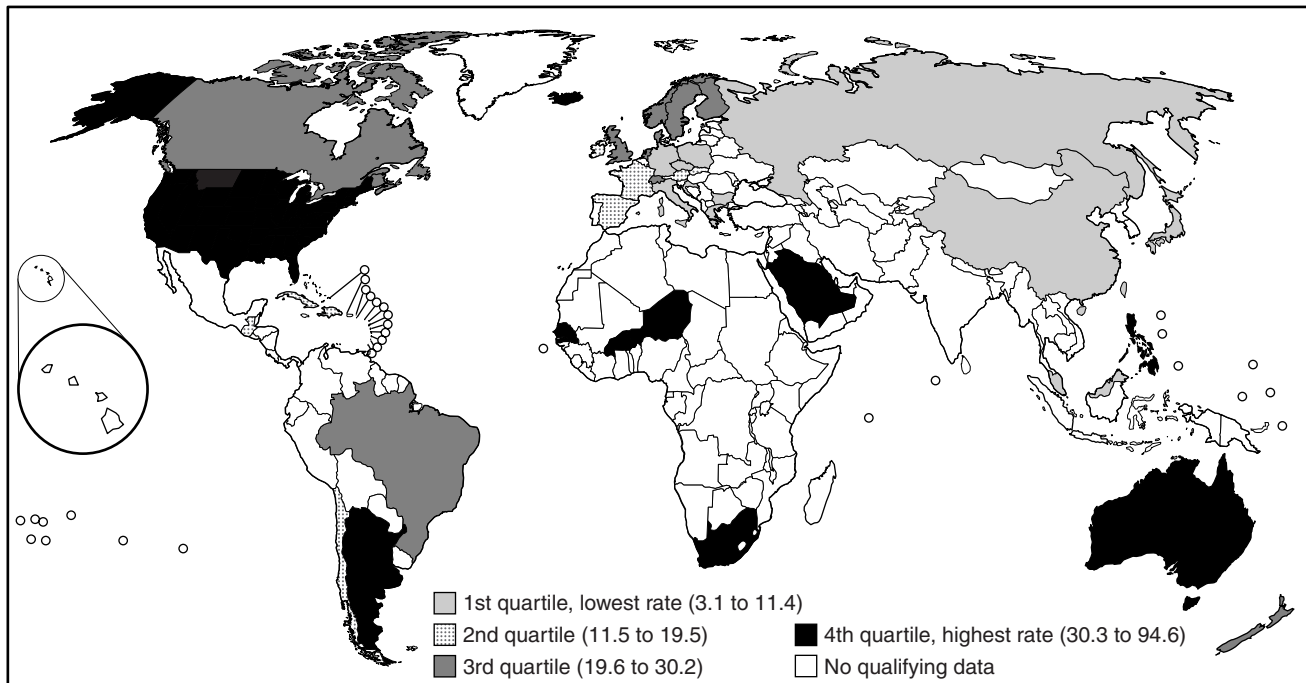

The older *H. aegyptius* is found within *H. influenzae* biotype III and is closely related to serotype c. It was initially described by Robert Koch in Egypt in 1883 during an epidemic of conjunctivitis and subsequently isolated by Weeks. It is still referred to as the Koch-Weeks bacillus. Genomic analyses suggest that *H. aegyptius* is identical to *H. influenzae* with DNA homology of 80% to 100%. In 1984, a new clonal epidemic strain of *H. aegyptius* with unique pathogenic properties appeared in Brazil,<sup>1</sup> causing Brazilian purpuric fever (BPF). The specific clone has caused all cases of BPF and has some unique features that differentiate it from other *H. aegyptius* strains, though its growth requirements appear to be identical to those of *H. influenzae*. BPF has declined in importance since the 1990s.

## EPIDEMIOLOGY

*H. influenzae* is part of the normal human nasopharyngeal flora and spreads by the airborne or direct contact routes from person to person. Nonencapsulated strains are frequently found in the upper respiratory tract. Among encapsulated strains, invasive type b is carried by 2% to 4% of children in North America. Carriage of type b organisms can occur in up to 30% of children in developing countries and in children in day-care centers in North America.<sup>2</sup> The Hib serotype causes most invasive disease, including bacteremia, meningitis, epiglottitis, pneumonia and empyema, septic arthritis, and cellulitis. In North America and Europe, the peak incidence of invasive Hib disease is from 6 to 12 months of age; in West Africa and India, the peak incidence is from 6 to 8 months.<sup>3,4</sup> Figure 28-1 and the map summarize data on incidence of Hib disease.<sup>5,6</sup> Among Eskimo and Native American children under 5 years of age, rates of Hib meningitis of up to 254 per 100,000 have occurred.<sup>6</sup> Data from developing countries are limited, but studies from Asia show lower incidences compared with Africa.<sup>6-8</sup>

**FIGURE 28-1** Incidence (mean, quartiles, range) of Hib meningitis in children under 5 years of age, by WHO region (excludes studies in special-risk groups). AMR, Americas; APR, Asia and Pacific Rim; EMR, Eastern Mediterranean region; EUR, Europe; SEAR, Southeast Asia region; WPR, Western Pacific region. (Adapted from *Haemophilus influenzae* type b [Hib] meningitis in the pre-vaccine era: A global review of incidence, age distributions, and case-fatality rates. WHO/V&B/02.18. Geneva, Switzerland, WHO, 2002.)

Country specific incidence, by quartile, of Hib meningitis per 100,000 children <5 years of age in the pre-vaccine era, 46 countries. (Adapted from *Haemophilus influenzae* type b (Hib) meningitis in the pre-vaccine era: a global review of incidence, age distributions, and case-fatality rates. WHO/V&B/02.18. Geneva, Switzerland: WHO 2002).

The epidemiology of *H. aegyptius* is not well described. It causes epidemics of purulent conjunctivitis, and outbreaks have occurred in both developed and developing countries. Preexisting trachoma is a major risk factor for epidemic conjunctivitis. In 1984, an outbreak of purpuric fever caused by *H. aegyptius* occurred in São Paulo, Brazil.<sup>9</sup> Although this organism is a common cause of conjunctivitis throughout the world, bacteremia was not reported prior to the epidemic of BPF in 1984. The majority of persons with conjunctivitis and with BPF have been children. The principal route of transmission seems to be direct inoculation from fingers to conjunctiva, but airborne spread may also occur.

## DISEASE

Unencapsulated *H. influenzae* strains may cause sinusitis, otitis media, and bronchitis and may also cause pneumonia in children in developing regions or in adults with immune defects. Hib strains cause meningitis, bacteremia, pneumonia, epiglottitis, septic arthritis, pericarditis, and occult febrile bacteremia, as well as placentitis and peripartum septicemia in mothers. A small proportion of invasive disease is caused by other capsular types, notably, a and f.

About half of all reported invasive infections caused by Hib are meningitis, and before the introduction of Hib vaccine, Hib accounted for the majority of childhood bacterial meningitis cases worldwide, outside the meningococcal belt of Africa.<sup>5,6</sup> The clinical characteristics of Hib meningitis are similar among children of developing or developed countries, although the case-fatality rates may reach 40% in the former. Complications include subdural effusions, and central nervous

system (CNS) sequelae occur in 11% to 40% of survivors of Hib meningitis, with deafness being a common finding. Hib epiglottitis was common in older children in North America and Europe but is rarely reported in developing countries.<sup>4</sup> Hib pneumonia is said to be infrequent in developed countries. However, in developing countries data on Hib pneumonia are mixed; lung tap and Hib vaccine studies indicate that Hib may cause from 4% to 30% of severe pneumonias in hospitalized patients.<sup>10–13</sup>

*H. aegyptius* produces a purulent vascular conjunctivitis, which often is bilateral and otherwise not pathognomonic. However, BPF is a unique syndrome.<sup>9</sup> It is a rapidly progressing illness with onset usually within a week of purulent conjunctivitis. Widespread petechiae followed by purpura, vascular collapse, and death usually occur within 1 to 2 days of the onset of the febrile illness. Although milder cases have been described, BPF appears to have a fulminant course with a high mortality rate.

## PATHOGENESIS

Carriage of Hib in the nasopharynx is mediated by pili, which facilitate attachment to epithelial cells, and an immunoglobulin (Ig) A1 protease protects the organism from mucosal antibodies. Carriage increases following infection with influenza or other viruses. Most carried strains are nonencapsulated. Following carriage, encapsulated strains may invade the bloodstream and infect secondary sites, whereas nonencapsulated strains mainly cause disease by contiguous spread.

Type b strains have a pentose polysaccharide capsule composed of repeating units of phosphoribosyl phosphate (PRP),

which is a critical virulence factor. The other serotypes have hexose polysaccharide capsules and are far less frequent in invasive disease. It has been known since the 1930s era of serotherapy that IgG antibody directed against the capsular polysaccharide can be used for therapy and is protective in an animal model. Specific anti-PRP antibody mediates opsonophagocytosis and is correlated with protection. The age-specific incidence of disease in human infants is inversely correlated with levels of serum anti-PRP antibody.<sup>14</sup>

*H. aegyptius* does not have a polysaccharide capsule, and the pathogenesis of conjunctivitis or BPF is not understood. The BPF clone has a lipooligosaccharide that varies significantly from non-BPF strains, and this clone possesses a unique pilin protein.<sup>15</sup> However, neither characteristic has been proved to have a specific role in its virulence. The role of host defenses is unknown.

## DIAGNOSIS

*H. influenzae* is diagnosed by microbiologic isolation of the organism from a sterile site such as cerebrospinal fluid (CSF), blood, lung puncture, joint, or bone. The characteristic small, flat, colorless colonies are seen on subculture on chocolate agar. Hib excretes capsular polysaccharide, which can be seen by antigen detection techniques with latex agglutination in the blood, CSF, and urine. The sensitivity of urine antigen tests is variable, and false positives may occur in colonized children or those who have recently received Hib vaccine.

*H. aegyptius* is diagnosed by culture, usually from the conjunctiva. The BPF clone is present in blood cultures from patients with the syndrome, as well as in conjunctival cultures.

## TREATMENT

Ampicillin or chloramphenicol has been the treatment of choice for all forms of invasive *H. influenzae* disease, but resistance to ampicillin emerged during the 1970s and to chloramphenicol in the 1990s and has reduced their usefulness in many regions.<sup>4,16</sup> Third-generation cephalosporins should be used for initial treatment depending on local susceptibility patterns. Cefotaxime 200 mg/kg/day in four doses or ceftriaxone 100 mg/kg once daily are regimens of first choice. Treatment for meningitis and sepsis syndromes should be continued for 7 to 10 days. Osteomyelitis requires a longer course of therapy, usually 2 weeks of parenteral therapy followed by 2 to 4 weeks of an oral regimen.

Controlled trials in children with Hib meningitis have shown that dexamethasone 0.15 mg/kg every 6 hours, given for 2 to 4 days with a third-generation cephalosporin reduces the occurrence of hearing loss, probably by modifying the inflammatory response. This may be less effective in the more advanced cases typically admitted to hospitals in developing regions.<sup>17</sup> *H. aegyptius* conjunctivitis has been treated both topically and systemically. Systemic treatment is preferred and, in particular, whenever outbreaks of BPF occur, systemic treatment is mandatory to forestall invasive disease. *H. aegyptius* has become resistant to ampicillin and chloramphenicol. Third-generation cephalosporins are effective alternatives. Trimethoprim-sulfamethoxazole can also been used for the treatment

of conjunctivitis. Therapeutic efficacy studies in BPF are limited. Supportive measures are critical, however, to ensure survival when the clinical syndrome has fully developed.

## PREVENTION

The virtual elimination of invasive Hib disease in many regions by vaccine is an outstanding success story of modern public health.<sup>14</sup> Polysaccharide PRP vaccines were effective in older children but were immunologically ineffective in infants at greatest risk. Conjugation of the polysaccharide to proteins stimulates a T cell-dependent antibody response in infants, with immunologic priming. Four different Hib PRP-protein conjugate vaccines effective in infants are now available. The vaccines have similar efficacy but differ in immunologic details. Hib meningitis virtually disappeared a few years after the introduction of protein-conjugated Hib PRP vaccines for infants in 1991 in the United States. This status was achieved even though the level of immunization among infants was lower than 80% in many urban regions, suggesting that reduction of carriage in vaccinees had a herd effect that resulted in protection of unvaccinated infants.<sup>18</sup> The experience of rapid disappearance of Hib meningitis within 1 to 2 years of introduction of routine immunization was replicated in Europe,<sup>19</sup> South America,<sup>20</sup> and West Africa.<sup>21,22</sup>

Current U.S. practice is to administer three doses of oligosaccharide-CRM<sub>197</sub> conjugate Hib vaccine (HbOC) or PRP-T vaccine at 2, 4, and 6 months of age or two doses of PRP-OMP at 2 and 4 months, with a booster at 5 to 18 months. Because of the success of universal infant immunization in developed countries, and the reports of high efficacy of Hib conjugate vaccine in the prevention of invasive disease,<sup>20,21,23</sup> the World Health Organization (WHO) recommends the use of this vaccine wherever Hib disease is present.<sup>24</sup> Hib vaccines combined with diphtheria-tetanus-pertussis (DTP) vaccine are in use in the United States, and combination vaccines with Hib, DTP, and IPV are available elsewhere.

Passive immunization with monthly injections of human IgG can prevent Hib disease although this is not feasible in developing regions. Preventive treatment of unvaccinated household infant contacts with rifampicin is recommended in North America to reduce the 1% to 4% secondary attack rate in household and day-care contacts.

*H. aegyptius* is spread by hands and fomites. Eye-to-eye transmission can be reduced by hand washing and early effective treatment.

# Calymmatobacterium granulomatis Infection (Donovanosis)

NIGEL O'FARRELL

## INTRODUCTION

Donovanosis is a cause of genital ulceration found in a few diverse tropical countries. The condition has been known under many names, including serpiginous ulceration of the groin, ulcerating granuloma of the pudenda, granuloma genito-inguinale, infective granuloma, granuloma inguinale tropicum, chronic venereal sores, granuloma venereum, and, more commonly, granuloma inguinale. This variation in terminology has led to many cases of donovanosis being mistaken for lymphogranuloma venereum (see Chapter 48), a condition caused by *Chlamydia trachomatis* serovars L1–L3.

Donovanosis was first described by Macleod, Professor of Surgery in Calcutta in 1882<sup>1</sup> and the causative organism was recognised by Donovan in Madras in 1905.<sup>2</sup> Until recently, the organism has been classified as *Calymmatobacterium granulomatis*, a gram-negative bacillus. However, based on evidence of a phylogenetic similarity of 99% with *Klebsiella pneumoniae* and *K. rhinoscleromatis*, a proposal has been put forward that the organism be reclassified as *K. granulomatis comb nov.*<sup>3</sup> Lesser phylogenetic similarities with *Klebsiella* spp. have also been reported and further confirmatory studies are needed to determine whether *C. granulomatis* is indeed a unique species.<sup>4</sup>

## AGENT

Classical Donovan bodies measure  $1.5 \times 0.7 \mu\text{m}$  and are usually found in macrophages and epithelial cells of the stratum malpighii. Characteristically there is a large mononuclear cell 25 to 90  $\mu\text{m}$  in diameter with intra-cytoplasmic cysts filled with deeply stained Donovan bodies.<sup>5</sup> Initial attempts to culture the causative organism were unconvincing until 1943 when Anderson reported its isolation on the yolk sac of chick embryos and proposed a new genus, *Donovania*, and species, *granulomatis*.<sup>6,7</sup> Electron microscopy studies typically show organisms with gram-negative morphology and a large capsule but no flagella. Filiform vesicular protrusions may be seen on a corrugated cell wall.<sup>8</sup>

## EPIDEMIOLOGY

Donovanosis has an unusual geographic distribution. Currently, it is found in Papua, New Guinea, South Africa—KwaZulu-Natal and Eastern Transvaal, parts of India and Brazil, and in aboriginal communities in Australia. Sporadic cases are occasionally reported elsewhere in Southern Africa, the West Indies, and South America. The largest epidemic recorded was in Papua, New Guinea, where 10,000 cases were reported in a population of 15,000 between 1922–1952.<sup>9</sup>

Following the recent move to syndromic reporting of sexually transmitted infections (STIs) in many developing countries, routine reporting of donovanosis has diminished considerably even in endemic areas. Prior to this change, a significant epidemic emerged in Durban, South Africa, where 3153 cases were reported from the main STI clinic in 1997.<sup>10</sup> Donovanosis also accounted for 11% and 16% of genital ulcers in men and women, respectively, in an earlier Durban study.<sup>11,12</sup> In Papua, New Guinea, the incidence of donovanosis is now decreasing but the condition was the second most common cause of genital ulceration in five health centers in 1989–1990.<sup>13</sup> In Pondicherry, south India, donovanosis accounted for 14% of genital ulcer cases in an STI clinic between 1993–1997.<sup>14</sup> In the Northern Territory region of Australia, reported cases decreased to less than 10 per year by 2002 from an estimated 300 cases in 1998, following the introduction of an eradication program.<sup>15,16</sup>

Donovanosis is generally regarded as an STI, albeit one with low infectivity. The case for sexual transmission is supported by the following: a history of sexual exposure before the appearance of lesions, increased incidence in most sexually active age groups, anal lesions in homosexual men practicing receptive anal intercourse, genital infection predominant, frequent concomitant STIs, and outbreaks linked to sex work. Although infection with donovanosis in sexual partners of index cases is not invariable, epidemiological treatment is advised, as lesions may not always be immediately obvious.

## DISEASE

The incubation period is uncertain. Experimental lesions have been induced in humans 50 days after inoculation and this duration is probably a reasonable estimate.<sup>17</sup> The condition usually starts as a firm papule or subcutaneous nodule that subsequently ulcerates. Four types of lesions are reported: (1) Ulcerogranulomatous—the most common type—beefy-red, nontender, fleshy ulcers that bleed readily to the touch; (2) Hypertrophic or verrucous type—usually with a raised irregular edge, sometimes dry; (3) Necrotic—offensive-smelling ulcer causing tissue destruction; (4) Sclerotic or cicatricial lesion with fibrous and scar tissue.

The genital area is affected in 90% of cases and the inguinal region in 10% (Fig. 29-1). The usual sites of infection are, in men, coronal sulcus (Fig. 29-2), prepuce, and frenum, and in women, the labia minora and fourchette. Cervical lesions are uncommon but may mimic carcinoma. Extragenital lesions occur in 6% of cases and are usually associated with genital disease. Sites of infection include lip, gums, cheek, palate, pharynx, neck, nose, larynx, and chest.<sup>18</sup> Lymph gland enlargement is uncommon. Disseminated donovanosis is rare

**FIGURE 29-1** Inguinal lesions of donovanosis.

but secondary spread to liver and bone may occur and is often associated with pregnancy and cervical lesions. Extragenital lesions may be difficult to differentiate from rhinoscleroma caused by *Klebsiella rhinoscleromatis*. Carcinoma is a serious but rare complication.

As a cause of genital ulceration that bleeds readily, it is not surprising that donovanosis is a risk factor for HIV infection. In Durban, the proportion of men diagnosed with donovanosis and HIV increased significantly as the duration of lesions increased suggesting that HIV was acquired through sexual intercourse despite ulceration.<sup>19</sup>

## DIAGNOSIS

In endemic areas, a clinical diagnosis of genital donovanosis by experienced observers has a reasonably high positive predictive value.<sup>20</sup> If possible, confirmation of the diagnosis should be made before antibiotics are given so that definitive treatment can be given. The diagnosis is made by identifying intracellular Donovan bodies, sometimes capsulated, within large mononuclear cells in smears obtained either from tissue smears or biopsy samples (Fig. 29-3).

Tissue smears can be performed cheaply and quickly in busy clinics. However, to achieve the maximum positive

**FIGURE 29-2** Typical penile donovanosis lesion.

**FIGURE 29-3** Tissue smear stained by rapid Giemsa (RapiDiff) technique showing numerous Donovan bodies in a monocyte.

yield, specimens must be prepared carefully. Debris should be removed from the ulcer by gently rolling a cotton-tipped swab across the lesion to minimize bleeding. Another swab should then be both rolled firmly across the ulcer to collect material and then across a glass slide so that material is spread evenly. The slide is air dried and stained by a rapid Giemsa method using eosin and thiazine solutions.<sup>21</sup> If multiple swabs are taken to detect other pathogens and donovanosis is suspected clinically, the tissue smear should be taken first so that an adequate amount of material can be collected.

In clinics where patients are likely to return, a crushed tissue smear using a slow overnight Giemsa method is preferable.<sup>22</sup> Pieces of tissue obtained by using a forceps and scalpel from the advancing surface of the ulcer are crushed between two slides and then stained.<sup>23</sup> If time and resources allow, biopsy specimens may offer a greater chance of confirming the diagnosis. The best stains to use are either Giemsa or silver. Histologic changes of donovanosis show epithelial proliferation with a heavy inflammatory infiltrate of plasma cells, neutrophils, and few lymphocytes. Biopsy is invariably required to confirm the diagnosis for necrotic and sclerotic ulcers and sometimes for hypertrophic lesions.

Culture of the causative organism has recently been the subject of a resurgence of interest. After a gap of 35 years, culture was reported from two centers in 1997—in Durban using a monocyte coculture system<sup>24</sup> and in Darwin, Australia, with a modified chlamydia culture system using human epithelial cell lines.<sup>25</sup>

Polymerase chain reaction (PCR) methods have also been developed for donovanosis.<sup>4,26</sup> In Darwin, amplification of *Klebsiella*-like sequences was achieved using primers targeting the *phoE* gene. A diagnostic PCR was developed using the observation that two unique base changes in the *phoE* gene eliminate *Hae*III restriction sites enabling clear differentiation from closely related species of *Klebsiella*.<sup>26,27</sup> A colorimetric PCR test has since been developed for use in diagnostic laboratories.<sup>28</sup>

Serologic testing with an indirect immunofluorescence method using tissue sections from known donovanosis cases has been undertaken but the sensitivity of this method is low for early lesions.<sup>29</sup> Other diagnostic methods, now

superseded, include antigen detection, complement fixation, and skin tests.

In communities where donovanosis is prevalent, practitioners should have a high index of suspicion and be able to make a reasonably accurate clinical diagnosis in most cases. However, other causes of genital ulceration—primary syphilis, condylomata lata of secondary syphilis (see Chapter 44), chancroid (see Chapter 27) and large HIV-associated herpes ulcers (see Chapter 76)—should also be considered. Amebiasis (see Chapter 86) and carcinoma may mimic necrotic donovanosis. Dual infection with one or more of the classical causes of genital ulcers should always be considered, particularly if there is a delay in seeking medical attention. In developed countries, a history of travel to and sex in an endemic country (see Chapter 132) may point to a diagnosis of donovanosis.<sup>30</sup>

## TREATMENT AND PROGNOSIS

WHO guidelines recommend azithromycin 1 g followed by 500 mg daily until all lesions have healed.<sup>31</sup> In Australia, either azithromycin 1 g weekly for 4 to 6 weeks or 500 mg once daily for 1 week were both effective.<sup>32</sup> The CDC recommends azithromycin 1 g weekly for at least 3 weeks or until all lesions have healed.<sup>33</sup> Other antibiotics should probably be given for 3 weeks or until all lesions are healed and include: co-trimoxazole 160–800 mg twice daily, ciprofloxacin 750 mg twice daily, doxycycline 100 mg twice daily. Gentamicin 1 mg/kg 3 times daily intramuscularly or intravenously can be given if there is no response in the first few days with other regimens. Ceftriaxone, norfloxacin, and trovofloxacin have also proved effective. Surgery may have to be undertaken for intractable lesions that cause gross tissue destruction.

The introduction of syndromic STI management has significant implications for the management of donovanosis. Traditional syndromic algorithms for genital ulcers have advised treating for syphilis and chancroid although, more recently, herpes management has also been included. Optimal treatment for donovanosis differs from chancroid and areas with significant prevalences of donovanosis should therefore have their own local algorithms that will ensure adequate treatment for possible cases. A good example of this local approach is in Australia where azithromycin is the drug of choice when donovanosis is suspected amongst aboriginals.<sup>16</sup> In the past, azithromycin has often been excluded from treatment protocols because of cost but its price has decreased considerably and it should now be the universal first choice treatment for donovanosis.

A neglected aspect in the management of donovanosis is the psychological distress to which some patients, particularly those with long-standing disease, are subjected to. The importance of case management for donovanosis is therefore still very important. Many patients present with long-standing disease and previously have sought health care elsewhere. In these cases confirmation of the diagnosis should be sought so that specific treatment can be given for donovanosis. Patients should be seen in a confidential setting and informed that they have an unusual condition that will respond to antibiotics over time. Poor genital hygiene may be a predisposing factor<sup>18</sup> and the need to wash behind the foreskin in men with subpreputial lesions should be mentioned. The report that azithromycin for 1 week is effective is particularly

important for the management of patients who have to travel long distances.

It is unclear whether HIV alters the response of donovanosis ulcers to treatment. In Durban, the clinical response to treatment was unaltered in HIV-positive pregnant women<sup>34</sup> but in India, ulcers in HIV-positive subjects took slightly longer to heal than in HIV-negative subjects.<sup>35</sup> Although there is no data about azithromycin for donovanosis in HIV-positive subjects, it would be surprising if it were not shown to be effective.

## PREVENTION AND CONTROL

The fact that significant numbers of donovanosis cases are found in only a few geographic locations makes the condition particularly suitable for targeted initiatives for disease control. In Papua, New Guinea, the large epidemic was controlled by annual examination, registration of the population, compulsory treatment, and assistance from the police in detaining patients reluctant to cooperate with the authorities.<sup>9</sup> Also in Papua, in the Goilala District, where 3.4% of the local population were infected with donovanosis, successful control measures included house-to-house visits with on-site medical examinations.<sup>36</sup> When antibiotics first became available in the United States, donovanosis elimination programs were initiated by some states. More recently a donovanosis eradication program targeting aboriginal and Torres Strait Islander populations in Australia commenced in 1996.<sup>16</sup> This intervention has reduced the number of cases significantly and owes much to strong political commitment supported with resources to heighten awareness of donovanosis at the primary health-care level.

Female sex workers have been implicated as source contacts of index cases in the United States<sup>37</sup> and Papua, New Guinea,<sup>38</sup> and usually have detectable lesions if infected. Clearly health-care providers working with sex workers in donovanosis endemic areas should be targeted to increase awareness of donovanosis.

Control of genital ulcers is one strategy that could be important in limiting the spread of HIV.<sup>39</sup> It is therefore noteworthy that the numbers of cases of HIV attributable to heterosexual sex is still very low in the Northern Territory, Australia, where a sustained program to eliminate donovanosis has now been in place for some years.<sup>15</sup> Global eradication of donovanosis remains a distinct possibility but will require significant inputs from those in endemic areas if it is to be accepted onto the WHO disease eradication agenda.<sup>40</sup>

# Pneumococcal Infections

ELAINE TUOMANEN  
KEITH P. KLUGMAN

## INTRODUCTION

Acute respiratory infections are the leading cause of infectious disease mortality<sup>1</sup> and morbidity among children in developing countries<sup>2</sup> (Fig. 30-1). Until 1965, acute respiratory infections caused 25% of all deaths in children younger than 5 years old in European countries with adult life expectancy greater than 45 years compared to 4% of childhood deaths in countries with adult life expectancy greater than 70 years. During the 1980s, acute respiratory infections caused a mean of 18.8% of mortality in children younger than 5 years old in developing countries.<sup>2</sup> An analysis has shown that the percentage of infant mortality attributable to pneumonia is increased as the infant mortality rate increases.<sup>3</sup> Most fatal pneumonia in children is caused by *Haemophilus influenzae* or *Streptococcus pneumoniae*,<sup>4</sup> and the pneumococcus is also the most important cause of pneumonia in adults.<sup>5,6</sup> The pneumococcus is also a leading bacterial pathogen in the cause of meningitis throughout the world, including tropical countries.<sup>7</sup> It is estimated that approximately three of every four children on Earth will have had at least one episode of acute otitis media by the age of 3 years and the pneumococcus is the leading bacterial pathogen responsible for between 25% and 50% of cases of acute otitis media.<sup>8</sup> The pneumococcus is an important

**FIGURE 30-1** Prevalence of pneumococcal infection in children.

cause of sinusitis<sup>9</sup> and can also rarely cause other infections, such as peritonitis (associated with infections of the reproductive organs<sup>10</sup> or with the nephrotic syndrome),<sup>11</sup> endocarditis, septic arthritis, osteomyelitis, epidural and brain abscesses, as well as soft tissue infections.<sup>12</sup>

## AGENT

The pneumococcus is a Gram-positive coccus that is usually identified on the basis of optochin susceptibility and bile solubility. It can also be identified by its reaction with specific antisera. There are 90 pneumococcal serotypes described.<sup>13</sup>

Although the first observation of the organism now known as *S. pneumoniae* was made by Klebs in 1875,<sup>14</sup> the significance of this observation eluded him<sup>15</sup> and the discovery of the organism is often credited to Pasteur<sup>16</sup> and Sternberg,<sup>17</sup> who in 1881 passaged the organism from human saliva in rabbits and noticed that it caused a fatal septicemia in the animals. After much debate, it was recognized in 1883 to be a cause of lobar pneumonia by Friedländer.<sup>18</sup>

Fifty years later, driven by a desire to understand the lethal events in pneumococcal pneumonia, Griffith<sup>19</sup> and Alloway<sup>20</sup> demonstrated that the capsular polysaccharide was the essence of virulence of pneumococci, and capsular production could be naturally transferred as a heritable trait by an exogenous chemical substance, the transforming principle. In 1944, Avery and colleagues<sup>21</sup> showed that the transforming principle was DNA. During the next 50 years, the study of pneumococcal infection produced the first nonprotein vaccine,<sup>22</sup> suggested mechanisms for the action of penicillin and antibiotic tolerance,<sup>23</sup> and uncovered the complex structure and inflammatory properties of gram-positive peptidoglycan.<sup>24,25</sup> Historically, the pneumococcus has thus provided a rich resource for the discovery of important tenets in medicine.<sup>26</sup>

## EPIDEMIOLOGY

Although primary immunodeficiencies, including immunoglobulin subclass deficiencies, predispose to pneumococcal infection, by far the most important risk factors in adults in developed countries are smoking and chronic obstructive pulmonary disease, as well as underlying systemic diseases such as liver failure, renal failure, alcoholism, sickle cell disease, lymphoma, and leukemia. Invasive pneumococcal disease is common, however, in crowded communities as disparate as the crowded huts of rural villages in Papua New Guinea<sup>27</sup> and the jails of modern urban America.<sup>28</sup> The disease is more common in winter, probably due to increased carriage<sup>29</sup> and increased antecedent viral infections at that time of the year.

The emergence of human immunodeficiency virus (HIV) infection as a specific risk factor for invasive pneumococcal disease was first described when an excess of pneumococcal pneumonias was found among patients with acquired immunodeficiency syndrome (AIDS) in 1984.<sup>30</sup> The incidence of pneumococcal bacteremia in AIDS patients was subsequently shown to be approximately 100 times greater than that in patients without AIDS.<sup>31</sup> In some African countries, HIV is now the dominant risk factor for invasive pneumococcal disease in adults<sup>32,33</sup> and children.<sup>34</sup> Risk factors for invasive pneumococcal disease in HIV-infected people include a CD4 count of less than 200 cells per microliter, a previous

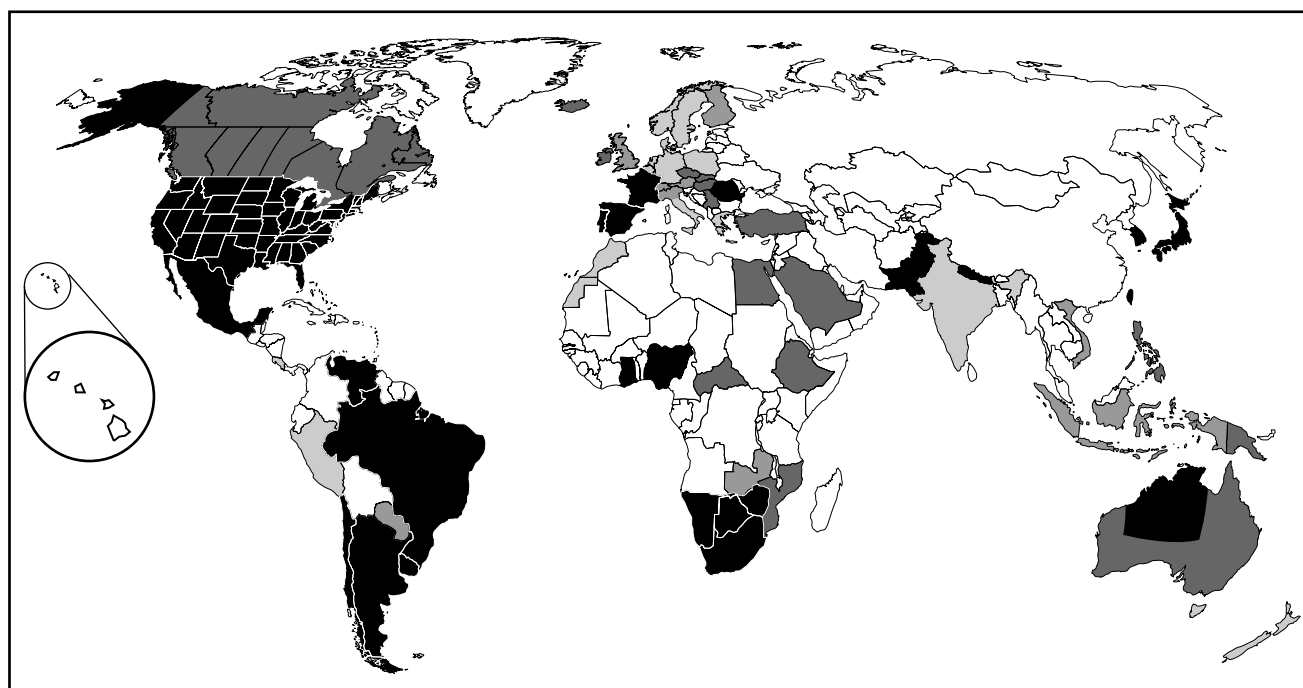

history of pneumonia, and a serum albumin value less than 3 g/dL.<sup>35</sup> HIV-infected patients with pneumonia have an increased incidence of bacteremia and, in particular, recurrent bacteremias.<sup>9,36</sup> In a study on invasive pneumococcal disease in a cohort of sex workers in Nairobi, there was a pneumococcal bacteremia rate of 2.38% per annum with a recurrence rate of 19.1% in those who previously had had pneumococcal bacteremia. The distribution of disease associated with bacteremia was somewhat unusual in that although the majority of cases had pneumonia, 30% had sinusitis and 11% had occult bacteremia.<sup>9</sup> These workers also noted a large decline in the CD4 count (mean of 105/ $\mu$ L) during the acute infection. HIV-infected patients usually respond well to standard antibiotic therapy.<sup>9,36</sup> Molecular analysis of repeat episodes of pneumococcal bacteremia in Kenya have documented reinfection with a serotype different from that previously isolated, coinfection with more than one serotype at the same time, and relapse with recurrent disease caused by a serotype identical to that previously isolated from the patient.<sup>37</sup> Data suggest that pediatric serotypes are more common in HIV-infected people,<sup>32,38</sup> particularly women.<sup>32</sup>

### Antibiotic Resistance

Penicillin resistance of the pneumococcus was first described by Hansman and Bullen in Australia in 1967.<sup>39</sup> Until the 1980s, the focus of resistance was Papua New Guinea, South Africa, and Spain<sup>40</sup>; although the incidence of resistance in most developed countries remained low, very few data were available from developing countries. The 1990s witnessed a

dramatic increase in resistance worldwide, including Southeast Asia.<sup>41</sup> Studies in Pakistan,<sup>42</sup> South Africa,<sup>43,44</sup> and elsewhere have documented a similar rate of resistance in isolates obtained from nasopharyngeal swabs from children attending outpatient clinics, or on admission to hospital, compared with isolates from blood and cerebrospinal fluid (CSF). This allows the possibility of determining the incidence of resistance in small field trials that focus on nasopharyngeal carriage. Such studies have been reported from many countries, including the Central African Republic,<sup>45</sup> Zambia,<sup>46</sup> and Malawi.<sup>47</sup> Although a direct association between the total use of antibiotics in a given country and antibiotic resistance has not been documented in developing countries, this association has been documented for the pneumococcus in Europe.<sup>48</sup> Antimicrobial agents are freely available in most developing countries, but there are some poor countries with populations not exposed to antibiotics and these populations may harbor pneumococci with very low levels of resistance. Such a situation has been documented in Lesotho<sup>49</sup> and in Nepal.<sup>50</sup> Macrolide resistance is increasingly common in pneumococci but may be expected to be more common in developed countries where these more expensive drugs are widely used. In developing communities, mass treatment with azithromycin for trachoma may increase the isolation of macrolides-resistant pneumococci, particularly if these strains are preexistent in the community.<sup>50,51</sup> Among the oral agents, resistance to trimethoprim-sulfamethoxazole is of particular concern because of its widespread use in the treatment of pneumonia, as prophylaxis in HIV-infected patients in developing countries, and its ability to select multiresistant strains.<sup>47</sup> Fansidar therapy for malaria

Global prevalence of penicillin resistance in the pneumococcus

- Unknown    ■ 10–25%
- <5%      ■ >25%
- 5–10%

has been shown to select trimethoprim sulfamethoxazole resistance in pneumococci isolated from the nasopharynx of exposed children in Malawi.<sup>52</sup>

## **PATHOGENESIS AND IMMUNITY**

Only with the very recent advent of genome sequencing and new genetic strategies amenable to mutation of gram-positive bacteria have the actual components of the pneumococcus that orchestrate disease become approachable. Sequences of several pneumococcal genomes have been published<sup>53,54</sup> and functional genomic screening, such as by signature tagged mutagenesis or microarray analysis, has identified many new virulence determinants and their regulatory mechanisms (Fig. 30-2).<sup>55–60</sup>

### **Targeting Pneumococci to Several Niches in the Host**

Pneumococci are harbored asymptomatically in the nasopharynx by approximately 50% of the population at any given time.<sup>61</sup> Pneumococci bind to nasopharyngeal cells by several protein “adhesins,” the most dominant of which is choline-binding protein A (CbpA). CbpA binds secretory component of IgA on the surface of the epithelium, allowing the bacteria to enter and translocate across the cell.<sup>62,63</sup>

Progression to overt disease is more frequent upon acquisition of a new serotype<sup>64</sup> or following a viral respiratory tract infection, particularly influenza.<sup>65</sup> On gaining access to the lung, pneumococci adhere to and invade cytokine-activated lung and endothelial cells by binding to the platelet-activating factor (PAF) receptor on activated cells. Pneumococci bound to the PAF receptor are internalized and migrate across eukaryotic

cells in a vacuole, suggesting this as a route of entry for invasive disease.<sup>66</sup> The ability of PAF receptor antagonists to block internalization and transmigration in vitro and to interrupt progression from pneumonia to bacteremia in animal models is consistent with this pathogenetic mechanism.

Invasion is the result of the coordinate activity of several virulence determinants. The activities of individual adhesive ligands appear to be controlled by several global regulatory pathways that adjust the bacterial surface composition in response to environmental cues.<sup>56</sup> High-frequency phase variation in colonial morphology is a marker for a reversible transition between virulent (transparent colonies) and avirulent (opaque colonies) phenotypes.<sup>67</sup> Modulation of virulence is also seen in mutants in two component signal transduction systems.<sup>68</sup> Invasion and host tissue damage are potentiated by the production of pneumolysin, a 53-kDa, thiol-activated, pore-forming cytotoxin, and by the production of hydrogen peroxide.<sup>69,70</sup> Once in the bloodstream, progression to pneumococcal meningitis usually occurs in conjunction with a high-grade septicemia. Invasion of the subarachnoid space may relate to the ability of the pneumococci to bind to and traverse cerebral vascular endothelial cells by binding to the PAF receptor using cell wall choline and CbpA.<sup>71</sup>

### **Inflammation in Response to Pneumococcal Cell Wall**

Whereas surface proteins are the key players in the recognition and invasion of host cells by pneumococci, it is the cell wall that is responsible for initiating inflammation. Like classic Gram-positive bacteria, the cell wall is composed of inter-linked disaccharide peptides that form a network.<sup>24</sup> This backbone is decorated with a polyribitol teichoic acid, which

**FIGURE 30-2** Pathogenesis of pneumococcal infection.

is unusual in that it contains phosphorylcholine.<sup>72</sup> The phosphorylcholine and the chemical composition of the cell wall building blocks are critical to the inflammatory activity of the cell wall.<sup>25</sup> The choline is also the docking station for the family of secreted choline-binding proteins. It has recently been realized that virtually all respiratory pathogens decorate a surface determinant with choline, presumably to avoid detection by the innate immune system's C-reactive protein.<sup>73,74</sup>

All the signs and symptoms of pneumococcal pneumonia, otitis media, and meningitis can be produced by instilling purified, protein-free pneumococcal cell wall into the appropriate organ.<sup>25,75</sup> The greater the release of cell wall during infection, the greater the inflammatory response and the more acute the course of disease.<sup>76</sup> This broad, potent inflammatory activity resembles Gram-negative bacterial endotoxin. The cell wall interacts with all elements of the acute inflammatory response. Components of the cell wall bind to CD14,<sup>77</sup> lipopolysaccharide (LPS)-binding protein,<sup>78</sup> and other soluble carrier proteins that then present the cell wall to Toll-like receptor 2.<sup>79</sup> Intracellular cell wall is recognized by NOD2.<sup>80–82</sup> These interactions activate transcription of acute phase response genes through NF- $\kappa$ B.<sup>80</sup> This results in the production of cytokines (particularly interleukin-1 and tumor necrosis factor), chemokines (such as PAF), and procoagulant activity.

Some secreted proteins and cell wall components are directly cytotoxic in that they kill eukaryotic cells. This toxicity can arise either by necrosis or by apoptosis. Pneumolysin and hydrogen peroxide and probably the cell wall have been shown to induce apoptosis of epithelial, endothelial, neuronal, and immune cells.<sup>83–85</sup>

## Clearance

Clearance of pneumococci involves recruitment of leukocytes in a  $\beta_2$  integrin-dependent fashion and subsequent phagocytosis. Depending on the chemistry of the capsule, phagocytosis can be averted or fail completely. The most virulent serotypes are 3, 4, and 6.<sup>86</sup> Type-specific anti-capsular antibody is the critical element in protective immunity. Phagocytosis is also promoted by the strong ability of the cell wall to fix complement and the ability of the acute phase reactant, C-reactive protein, to bind to the phosphorylcholine of the pneumococcal teichoic acid.<sup>87,88</sup> Furthermore, the teichoic acid serves as a ligand for the defense collagens (mannose-binding protein, macrophage scavenger receptor, and surfactant protein D), which accelerate clearance.<sup>89,90</sup>

## DIAGNOSIS

Pneumococcal infections are diagnosed primarily by culture of the organism from appropriate clinical samples, such as CSF, blood, pleural fluid, or purulent sputum. Confirmation of a pneumococcal cause of otitis media requires tympanocentesis. Although not routinely used diagnostically, lung puncture is required to establish the true cause of pneumonia. Other approaches to diagnosis include the detection of pneumococcal antigen, especially in CSF, and interest has recently focused on the molecular diagnosis of pneumococcal infection using the polymerase chain reaction (PCR). In this regard, a number of genes have been used as targets, including the autolysin and pneumolysin genes,<sup>37</sup> the penicillin-binding protein 2B gene,<sup>38</sup> *lytA*,<sup>91</sup> *psaA*,<sup>92</sup> DNA polymerase 1,<sup>93</sup>

and the 16S recombinant RNA gene.<sup>94</sup> Detection of urinary antigen may be useful in adults.<sup>95</sup>

## DISEASES: TREATMENT AND PROGNOSIS

### Meningitis

The mainstay of treatment of pneumococcal meningitis in developing countries has been intravenous penicillin or ampicillin, usually given in combination with chloramphenicol. The emergence of penicillin resistance led to a prospective comparative study of the outcome of the combination of penicillin and chloramphenicol in the treatment of penicillin-resistant versus penicillin-susceptible pneumococcal meningitis. This study showed that patients with penicillin-resistant strains responded poorly to the combination of penicillin and chloramphenicol, with 80% of patients having a poor outcome without change of therapy.<sup>96</sup> The bactericidal activity of chloramphenicol appears to be diminished against penicillin-resistant strains.<sup>96,97</sup> This has led to the situation that the third-generation cephalosporins, cefotaxime, or ceftriaxone are preferred in the management of pneumococcal meningitis where resistant strains are common. The decision as to which drugs can be used for empirical therapy will depend on the resources of the country and the knowledge of the prevalence of resistant strains in that country. The emergence of cephalosporin resistance in pneumococci in the United States,<sup>98</sup> together with evidence of increased CSF bactericidal activity against these strains after the addition of vancomycin,<sup>99</sup> suggests that vancomycin should be added empirically to cephalosporin for management of pneumococcal meningitis. The decision to use combination therapy will depend on the prevalence of strains with minimum inhibitory concentration of cefotaxime or ceftriaxone greater than 2  $\mu$ g/mL. Dexamethasone is widely given as adjunctive therapy for the management of pneumococcal meningitis, and a meta-analysis supports the use of the drug for 2 days in the treatment of childhood pneumococcal meningitis,<sup>100</sup> as does a more recent study in adults.<sup>101</sup>

### Pneumonia

The clinical spectrum of pneumococcal pneumonia is wide, including a rapid onset of high fever with rigors in young adults and an insidious disease with few physical signs in the elderly. Splenectomized patients are at risk of particularly rapid-onset disease. Signs associated with greater severity of disease include age older than 65 years, underlying illness, a respiratory rate greater than 30 breaths per minute in adults, shock, multiple organ involvement, multilobar disease, and a poor white blood cell response (less than  $4 \times 10^9$  cells per liter).<sup>102</sup>

Empirical treatment for moderate pneumonia in many developing countries has been trimethoprim-sulfamethoxazole. Although data are lacking on the impact of resistance to this drug combination on the outcome of pneumonia therapy, the drug fails to eradicate resistant pneumococci from children with otitis.<sup>103</sup> Also, because pneumococcal resistance to  $\beta$ -lactams does not influence the outcome of pneumonia treated with these agents,<sup>104</sup> oral amoxicillin appears to be the drug of choice and indeed has been shown to be superior<sup>105</sup> for management of pneumococcal pneumonia in the outpatient setting.

Intravenous management with penicillin or ampicillin is appropriate treatment for severe infections. In penicillin-allergic patients, new fluoroquinolones that are highly active against pneumococci are probably the drugs of choice,<sup>102</sup> although their cost may be prohibitive in developing countries. Very severe pneumonias may be treated with combination therapy using a  $\beta$ -lactam and macrolides based on observational studies,<sup>106,107</sup> but prospective randomized trials of combination therapy have not been performed.

### Otitis Media

In terms of the penetration of drugs into the middle ear, the spectrum of activity of different agents against pneumococci, and retained activity against resistant strains, high-dose amoxicillin is the most appropriate oral agent for the management of otitis media.<sup>108</sup>

### PREVENTION AND CONTROL

Pneumococcal disease was the first infection to be prevented by a nonprotein vaccine. Due to the work of Griffith, Tillet, Finland, Heidelberger, MacLeod, and Austrian, the capsular polysaccharide has come to be recognized as a critical component of vaccine efficacy (reviewed in Musher and associates<sup>109</sup> and Broome and Breiman<sup>110</sup>). The geographic distribution of serotypes differs by region, making a universal vaccine based on a reasonable number of capsular types complicated and costly to compose.<sup>111</sup> The currently approved vaccines consist of the capsular polysaccharides from 23 of the most common serotypes.<sup>110</sup> After many comprehensive studies, there is now overwhelming evidence that this vaccine is approximately 60% efficacious for protection against invasive disease in the general population, but it fails to protect the segments of the population most susceptible to disease: children younger than the age of 2 years or the elderly who are medically compromised.<sup>110,112–114</sup> The vaccine also does not protect against pneumonia,<sup>115</sup> and it may enhance disease in HIV-infected people who are not on antiretroviral therapy.<sup>116</sup> The basis for the ineffectiveness is the inability to elicit a T cell–dependent immune response. This can be overcome by conjugating a protein to the polysaccharide, a process successfully used to introduce a seven-valent pneumococcal vaccine in the United States in 2000.<sup>117</sup> Seven- and nine-valent pneumococcal conjugate vaccines are highly effective in preventing sepsis and meningitis in children due to vaccine serotypes,<sup>118,119</sup> even in HIV-infected children.<sup>119</sup> The vaccine reduces radiographically proven pneumonia by 25% in fully immunized children<sup>119</sup> and induces herd immunity in the population.<sup>117</sup> Although the vaccine reduces pneumococcal otitis, its overall efficacy against otitis is reduced by serotype replacement.<sup>120</sup> A major pneumococcal virulence determinant optimal for vaccine formulation remains to be identified. The advantage of choosing a pneumococcal protein determinant is that protection may be extended to capsular types not in the vaccine formulation.

Antibiotic prophylaxis has been attempted in communities such as Papua New Guinea with high rates of disease,<sup>27,121</sup> but because of the emergence of resistance it is reserved for patients at particularly high risk, for example, children with sickle cell disease.<sup>122</sup> These patients require pneumococcal vaccine after 2 years of age<sup>120</sup> and are a priority group to receive conjugate pneumococcal vaccine. Conjugate vaccines have

also been shown to interrupt the transmission of antibiotic-resistant strains<sup>123–125</sup>; however, cost remains a major barrier to their introduction in developing countries. A recent study has shown that conjugate vaccine reduces hospitalization of children with viral-associated pneumonia, presumably by preventing pneumococcal superinfection.<sup>126</sup>
